Other food production regimes from which horticultural societies are distinguished include gatherer-hunters and pastoralists (Sutton and Anderson, 2004: pp. 125–289), all of which support lower population densities than industrial-urban systems. These categories were bequeathed to us by Victorian scholars who thought of them comprising an evolutionary hierarchy, putting horticultural societies somewhere in the middle of the range between the gatherer-hunter and industrial-urban poles. This scheme continues to inform thinking to the current day (as evidenced by articles in this encyclopedia), and underpins notions of development conceived as facilitating the passage of communities to the industrial-urban pole. Anthropologists continue to use it although uneasy with the continued evolutionary implications, arguing that we should not judge urban-industrial life, notably liberal market democracy, as the superior socioeconomic order to which all human beings should necessarily aspire. It is an approximate classification scheme. We know, for instance, that Australian Aborigines (taken as a classic example of hunter-gatherer life) managed natural resources using fire to promote new vegetative growth, following what is dubbed a 'firestick farming' regime, and harvested in a way that ensured plants such as yams reproduced optimally next season (Gammage, 2011). At some hazy point, populations are thought to manage their natural resources sufficiently closely to be practising farming; this is accompanied by a more sedentary lifestyle. They qualify as horticultural societies when they emphasize crop cultivation over animal herding, although mixed arable and livestock farming is common. The label horticultural society covers a wide range of different subsistence regimes and sociocultural orders. The term is more commonly used in North America than Europe, where instead of lumping these regimes together, it is more usual to distinguish the different socioagronomic orders discussed below.

Agronomic Regimes

We find varying degrees of sedentariness among people who depend largely on cultivation to supply their food. The variation informs a preliminary distinction between different horticultural strategies. There is also some correlation with increasing population densities.

The places where we find the least permanent settlement and physically most direct technologies have cultivation systems that fallow the land not by rotating crops but by

rotating land use. We call this type of horticulture **shifting cultivation**, because after people have grown crops and fertility declines and yields start to fall (these cultivators not using any imported fertilizer to supplement the soil's nutrients), they abandon the plot to the forest and move elsewhere to clear a new garden on fresh land. Secondary regrowth meanwhile recolonizes the abandoned area, which may be left fallow for tens of years to allow nature to restore its fertility; following which it may be cleared and planted again in the next generation. Shifting cultivation is labor intensive, featuring hand tools, such as axes, machetes, hoes, and pointed digging sticks. We find a sexual division of labor, orchestrated into a joint effort. Men usually do the heavy axe-related work. They fell the trees and clear the forest. They also enclose the area to be gardened with rough fencing if this is necessary to keep out animals. The subsequent burning off of the dry and dead vegetation cleared from the plot is often done by both men and women working together. This burning is an important step, reducing standing vegetation to ash, which is readily mixed with the soil, liberating locked up nutrients in a form more available to planted crops. The release of nutrients (such as nitrogen, potash, phosphorus, etc.) through burning has led to the coining of the term 'swidden' to describe this type of cultivation. (Swidden is an old English word meaning to burn.) Following clearing and burning off, women usually take over and are responsible for breaking up the soil, planting crops, weeding, and finally, harvesting the plot. People living around the world in Asia, Africa, the Pacific, and Latin America grow a large variety of crops using this cultivation technique: for example, grains such as corn, millet, and sorghum; roots such as manioc, yams, and sweet potato; and fruits such as bananas, pawpaws, and melons.

Many Amazonian Indian populations practice shifting cultivation, horticultural crops supplying the bulk of their food regardless of the time spent gathering and hunting in the surrounding forest (Watters, 1971). Among the Yanomamo, plantains and bananas are the staple crop. They select well-drained sites, relatively clear of thorny underbrush. They do not attempt to burn large tree trunks, left strewn across plots in a jumble, serving as boundaries between patches of crops that belong to those who plant them. Newly established gardens yield crops in cycles, the rapidly growing ones such as maize coming first, followed by others including manioc, taro, sweet potato, and mapuey. The Yanomamo also grow chewing tobacco, cotton for hammock yarn, drugs for shaministic rituals, and many fruits including papaya, avocados, gourds, and hot peppers. A garden produces constantly as it matures, but a regular supply of food demands careful management. Gardens have direction, moving little by little as people gradually abandon older areas as thorny underbrush encroaches. They constantly clear adjacent land and transplant secondary plantain suckers as they appear. Sometimes, villages are obliged to establish new gardens elsewhere. This is usually a political decision, communities moving when threatened by raids from enemy villages. It requires a large effort to establish a new garden some way off, to transport needed cuttings and seeds. New gardens also produce sporadically at first, and people may face hunger, whereas established 'rolling gardens' offer predictable subsistence.

At some ill-defined point, agronomists distinguish **bush fallow** systems. These are broadly similar to shifting systems regarding technology and cropping strategies but with a reduced fallow interval and longer periods under cultivation. Instead of one or two years under cultivation followed by two or more decades under fallow forest, these horticulturalists may farmland for 5 to 10 years with a fallow interval of similar duration under bush or savanna vegetation. Stock such as cattle, goats, sheep may graze on the fallow. Settlement is increasingly stationary, and land holdings are usually more clearly defined with agreed field boundaries. These fallow systems sometimes evolve from shifting regimes with increasing population densities. They may demand management of soil fertility through manuring or fertilizer application, otherwise yields will decline over time. Degradation of the natural resource base may occur with increasing population pressure and demand to grow cash crops.

Again, at some ill-defined point, we distinguish **ley** systems. These are ones in which farmers systematically use the land to pasture livestock during the nonarable phase. At one end are unregulated leys where people graze their animals on unmanipulated natural regrowth of grasses and herbs. They have communal grazing rights, and practice little pasture management. At the other end are regulated leys where farmers manage the grazing vegetation, frequently putting down grasses and legumes as fodder. They maintain individual pastures, which they may fence off. They may graze meadows directly or use them to produce hay or silage. At this point, we usually think of them as agricultural regimes.

Bush fallows and unregulated leys are common in interlacustrine East Africa (Allan, 1967). The Lugbara, for example, have fields and homesteads scattered across open upland country. Homesteads comprise compounds, clusters of family huts and granaries, under which are ghost shrines and magical plants. Fields surround them. Each homestead cultivates three types of fields. Men do the heavy work of opening the land, women weed and harvest. Both sow, depending on the crop, men more handling cash crops. They intercrop in all. Postharvest care and use of crops are the responsibilities of women. The 'riverine fields,' irrigated by channels from streams, are highly fertile and need only short fallows; they support sweet potato, maize, sugarcane, and bananas. The 'home fields' fertilized with ashes and manure support nutrient-demanding crops such as beer brewing white sorghums. The 'outside fields' support staple eleusine, together with sorghum, simsim, and pigeon pea, cultivated for 2 or 3 years, after which they are left under bush fallow to restore fertility. People allow unregulated grazing of cattle and goats on fallow. They recognize different fallows, from recent and regaining fertility; to areas a few year old, the presence of certain plants showing restored fertility; through to cleared land left for a few months before hoeing; and finally uncultivated land. Each woman in a homestead should have areas in all fields, of equal fertility. If not, quarreling is likely. The fields of a homestead are likely to be scattered, due to differences in soil and water. This sets a limit on the maximum size of farming groups. A household short of certain farmland may move and take up residence with kinsmen elsewhere, usually a wife's or mother's brother.

It is generally agreed that with the invention of the plow and particularly associated agricultural machinery we enter the realm of **agriculture**. The plow allows people to harness either the strength and energy of draught animals or engine-powered machines to assist in their preparation of land for the planting of crops. The result is that one person, together with his team of oxen or whatever, can accomplish considerably more work alone, releasing others to follow other occupations. We have the emergence of increasingly specialized labor, a move from so-called organic to mechanical solidarity. We find the practice of crop rotation and occasional fallowing to maintain soil fertility, together with the increasing use of amendments such as manure, fertilizer, biocides, and so on. In regions that suffer water deficits, people may have irrigation technologies. In some places there are plantations of perennial commercial tree crops. The upshot is permanent farming, with clearly demarcated fields. While it is inappropriate to go into the growth of the first civilizations among the early cultivators of the Middle East, Mesoamerica, and the Far East, we should note some of the consequences of these developments, founded on a settled agricultural way of life (Cowan and Watson, 1992). They allowed for greater population densities, which, combined with the relative permanence of settlement that results with agriculture, led to the emergence of wider-scale political groups than based on the family or tribe. These developments opened the way over millennia to the evolution of industrial-urban societies, sometimes with associated peasantries.

Before turning from the agronomic aspects of horticultural societies to consider the social orders associated with them, it needs to be stressed that while the foregoing regimes have been presented with an evolutionary dimension it would be wrong to consider them as discrete steps leading from shifting cultivation to mechanized agriculture. This typology is no more than a low-level generalization by which we can usefully classify cultures. When we look closely we find that many societies do not fit comfortably into any one category but span two or more, as the East Uganda example illustrates. In the Baliem valley of New Guinea too, where sweet potato is the staple and people herd pigs, we find three sorts of cultivations. The largest are the permanent plots on the valley floor, some of which the Dani recultivate immediately upon harvest and others they leave fallow for months, even years. These gardens feature elaborate ditch systems that drain away/store water, delineate and protect cultivations from pigs and serve as mulching basins supplying organic rich mud for slopping over beds to ensure continued fertility. Other gardens men clear in a classic shifting mode on the mountain slopes, burning off plots and planting for a year or two. The third and smallest are kitchen gardens maintained adjacent to houses supporting a wide range of valuable crops such as tobacco, sugarcane, and bananas, continually fertilized with household waste. Households commonly have several different widely separated fields at different stages.

Sociocultural Orders

We now turn briefly to look at the gross nature of the social orders found associated with horticulturalists. It is difficult to distinguish between above horticultural regimes according to political economy (how people distribute resources). They occur in one of three broad categories: egalitarian with balanced reciprocity, chiefdoms with redistribution systems, or peasantaries in nations with markets. There is some correlation between permanence of settlement, cultivation regime and polity, with shifting cultivators frequently living in egalitarian orders and ley farmers in chiefdoms.

The **egalitarian societies** featuring balanced reciprocity are characterized by groupings commonly called tribes. These are relatively large groups of people (i.e., in comparison to hunter-gatherer bands), who occupy specific territories, where they lay specific claim and rights to resources. Characteristically these societies recognize all individuals as equal and place no persons above others, with authority and power to rule over them. They are what we call stateless or acephalous, and have evolved various strategies to maintain social order without formal government, judiciary, and so on; employing, for instance, descent and age in Africa, and sociopolitical exchange in Melanesia. The productive group is not the tribe, but usually the family, with some help from extra kin in occasional large cooperative ventures. Under this household mode of production, farmers consume most of their produce, although they distribute some to others. The formal distribution of food and goods is likely to be significant, taking place predominantly in reciprocal transactions. Relatives and friends who give things to one another keep a careful account. They give, not with the expectation of receiving an immediate return gift (or payment), but with the expectation of an equal return sometime later. There is often a competitive element in these transactions, those doing best winning higher status. They sometimes constitute grand institutions and are attended with some ceremony. Exchange is a facet of social and political relations and may exist independently of material wants and needs. This takes us away from subsistence and horticulture toward sociopolitical issues.

In Melanesia, sociopolitical exchanges featuring balanced reciprocity characterize the social order. Among New Guinea Highlanders, for example, each Dani family supplies its own food, and provides its own shelter. It occupies a compound with men's and women's houses, and pig sty, often comprising several related families and friends. Clan affiliation determines access to land and all have equal rights. These are rights of usufruct, not land ownership. Men do the heavy, spasmodic garden and construction work, and are more involved in public activities such as politics, disputes, and rituals. Women undertake routine cultivation work and domestic responsibilities, herding pigs and tending family needs. There is little call for distribution of goods with this minimal sexual division of labor. There is some trade with people elsewhere for a few imported goods. Sometimes, friends and neighbors make up a cooperative work party to garden or build a house. But there are no leaders. The Dani combine for conviviality, each person doing the same thing, the output comprising the sum total of their efforts (it is more fun mudding gardens together for example, even though this is a one-man job). Hostilities are common, fighting with bows and arrows and spears. Exchange promotes social order, primarily featuring pigs, which are usually killed on ceremonial occasions. The giving-and-receiving of animals constantly refurbishes the social network; people are bound to one

another through their lifetimes by the exchange of hundreds, even thousands, of pigs.

The **chiefdoms** with redistribution systems are hierarchically organized societies, where persons occupy different social ranks. In the top rank are the rulers, commonly called chiefs. These persons have authority vested in them, often sanctioned by some supernatural connection, and govern in a manner those living in their chiefdom, kingdom, tribe or whatever. Everyday rule is usually delegated locally to middle rank persons, who are responsible for day to day government, administration of justice, and so on. These chiefdoms are often feudal in nature, with these local leaders owing allegiance to the chief and supplying a military force if required by him. Societies organized in this way exploit raw materials on a larger scale. They do this, for example, by territorial conquests (as epitomized by the Zulu under their king Shaka) and through extensive trading networks (e.g., the Aztecs controlled mining activities as far away as northern Mexico). These societies can also organize larger productive groups, through the authority of their rulers, who by so doing, not only facilitate cooperation but also provide some sort of rationale for the existence of their power (e.g., the farming terraces, irrigation works, storehouses for produce, etc. constructed by the Inca). Redistributive systems predominate in these societies, where those of lower rank give food and goods to those higher in the form of tribute. The chief will rearrange everything he receives and add to it any surplus goods, which his probably superior productive position supply (i.e., from his large, communally worked gardens), and then redistributes it all to his subjects (usually via local-level officers in his government).

The chiefdoms of South Africa are good examples of this political order. The horticulture practised is broadly similar to East Africa, the main crops being maize and millet; together with groundnuts, gourds, sugarcane, and pumpkins. Farming is seasonal, dependent on the summer rains. One source of rulers' political authority is the belief that they can control the advent of the rains. Many have a precarious existence; food supplies fluctuating annually between plenty and scarcity bordering on famine, the Swazi for example talk of lean summer months as the time 'to swallow the pickings of the teeth.' Horticulture is not a prestigious occupation and is left primarily to women, whose main tool is the iron hoe. Except that is for plowing, which involves highly valued oxen handled by men, and the cultivation of cash crops, notably tobacco and cotton. Households cultivate large fields using ox-drawn plows. The power of rulers also relates to their right to allocate land to their subjects, who depend on it for their livelihood. The Swazi say that their political overlords 'serve' them the land, securing their rights by allegiance and usage. Women are allocated garden areas by their husbands at marriage. Homestead plot size depends primarily on supply of resident labor. People use grazing lands communally. They value pastoralism highly, having the so-called African 'cattle complex,' these animals have great symbolic value being exchanged to ratify marriage, sacrificed to propitiate ancestors, and paid in tribute to rulers. They call the king the 'Bull' of the nation, and the royal herd far exceeds any other, supplying animals redistributed to subjects at national events and sacrifices. In addition to sex and age, pedigree also structures the division of labor. Men and women cooperate in agriculture, man's work is heavier and more spasmodic, woman's routine and more continuous. Aristocrats do not engage in manual labor to the same extent as their subjects, they are responsible for successfully organizing their efforts, supervising work parties, and arranging for specialists to doctor land and seed. The rulers have several 'gardens of kingship' in different localities, which local headmen maintain by arranging their communal cultivation. Homesteads rely on kinsmen and neighbors to assist at bottlenecks; customarily organized into two competitive work parties they spur each other on in songs, rhythmically coordinating their work through music. The size of communal work parties reflects status; they enhance prestige, being rewarded with beer and food at the host's home.

The **peasantaries** associated with markets are also incorporated into hierarchically organized societies. They are usually incorporated within nation states where they occupy marginal and low positions, relatively powerless, and commonly exploited. These horticultural communities are in peripheral, underprivileged situations, frequently taken advantage of, even abused by, the dominant society. They usually feature poverty. Peasants depend in some regards on economic and political institutions beyond their local control. These bodies, which rule significant aspects of their lives, may supply them with certain services. Persons may participate in informal reciprocal exchange networks within their communities, but outside they are obliged to engage with impersonal commodity markets. While they supply their own subsistence needs, like tribespeople – from whom many of the Third World's peasants have descended in recent times – they are obliged also to cultivate a surplus to sell on outside markets to earn cash. In addition to using this money to purchase goods manufactured elsewhere, they also need some cash to pay the taxes levied on them by the colonial/national governments to which they are subject. They may also need to purchase outside inputs, such as inorganic fertilizers and biocides, to maintain their yields, especially if their farming system is under increasing demographic pressure, perhaps resulting in increasing environmental degradation, or subject to enforced 'development' (such as having to cultivate 'high-yielding varieties'). This may contribute to growing poverty. What peasants receive financially in return for their surplus horticultural produce is on the whole unfair, the élite making a disproportionate profit to support their privileged position and lifestyle by controlling access to imperfect markets and the arrangements for the distribution of produce.

The Mayan Indians of Mexico have occupied a peasant status increasingly since the Spanish conquest (Vogt, 1990). They sell crops surplus to their subsistence needs, largely maize and beans, and trade evaporated salt at fiesta day markets. In turn they purchase goods such as coffee, sugar, fish, liquor, and bread. They have been involved in marketing for centuries, historical evidence showing that they traded with Aztecs in pre-Hispanic times. Maize is their staple, believed to have an 'inner soul' in the ear, together with beans, squashes, chiles, chayotes, and fruits such as peaches. They keep chickens and pigs, and sheep for wool woven into *chamarras*, blankets and shawls, and mules for carrying heavy loads. The Mayans cultivate three types of land: small individually owned garden plots located near Highland homes, their ancestral patrimony; larger *ejido* plots acquired during the 1940s agrarian reform program, allocated by local

committees to households; and plots in the lowlands rented from wealthy *Ladino* landowners by patrilineal groups, which they divide equally among themselves. They use centuries' old swidden techniques, working with axes, machetes, bill hooks, and hoes. After cutting and burning vegetation, they plant using pointed digging sticks. In old fields they cut and rake maize stubble into piles for burning, and then hoe sheep manure into the turned topsoil. They prepare fields for planting at the onset of the rainy season. Ritual attends planting, a critical task in which a shaman offers candles, incense, liquor, and prayers to the Earth owner, who controls wind and clouds. People cultivate fields for varying periods of time, depending on elevation and soil quality, before allowing brush to grow again. They store threshed maize in granaries or indoor grain bins prior to sale.

Again this sociocultural typology, like the previous agronomic one, is only gross, the elements constituting approximate cultural sets, which have proved useful in organizing our ideas over many years. It continues to structure our thoughts in a preliminary fashion. There is some broad correlation between peoples' horticultural arrangements that is, how they produce food and other items necessary for life, and how they are socially organized, both to effect production and to achieve distribution of its fruits. But this is not to imply, as some writers argue, that mode of production determines the nature of social arrangements. Furthermore, many of these societies have undergone substantial social change under colonialism and subsequently globalization.

Future Directions

Several questions remain to be answered about horticultural societies, particularly with the occurrence of extensive social change. Many aspects are still poorly understood, insight sometimes blinkered by orthodoxy. The Baliem Valley for example supports one of the highest population densities in New Guinea ($\sim$160 persons km^{-2}), with no evidence that it is pushing against the environmental limits. How can the region's intensive horticulture system support such a high population density without any outside fertilizer amendments? The accepted shifting cultivation model, which pertains to this part of the world, predicts evidence of environmental strain, of the kind commonly associated with overpopulation. Yet the Highland region's sophisticated horticultural regime maintains soil fertility sufficient for the repeated cultivation of some crops (Sillitoe, 2010).

A major contributor to our understanding of horticultural societies beyond anthropology and geography has been 'farming systems research' conducted under the aegis of international development agencies (Shaner et al., 1982). This involves multidisciplinary teams, using survey techniques largely, to detail the ecological, technical, and socioeconomic aspects of horticultural regimes and identify constraints on production amenable to scientific research. It was initially associated with 'modernization,' seeking to advance the development of horticultural societies into commercial agricultural ones. It was thought that this would alleviate poverty, leading to increased production of a food surplus necessary to support increasing urban populations. To this end, agricultural research institutes worldwide embarked on programs to breed new 'high yielding varieties' of crops and develop associated technologies to increase production. The scientifically successful 'green revolution' resulted, diminishing the threat of famine. Nonetheless while it benefited wealthy landowners, it largely passed poor farmers by. It also worryingly increased dependency on outside manufactured inputs (inorganic fertilizers, fossil-fueled machinery, chemical pesticides, and herbicides) and gave rise to concern about long-term sustainability with evidence of increasing environmental pollution, susceptibility to mutated pathogens, insecure supply of needed inputs, and so on. There is a danger that the current push for genetically modified crops may exacerbate these problems. The move toward cash cropping also put farmers at the mercy of market fluctuations, sometimes causing their families considerable hardship, further increasing resistance to modernization's inducements to embrace commercial production.

There are growing concerns about the sustainability of various horticultural regimes, and other livelihood strategies, with changes that are occurring to the natural environment globally, largely resulting it is thought from human activities. Currently popular, and regularly featured in the media, is global climate change, which if meteorologists' modeling predictions are accurate, will have far reaching ecological consequences. Others are pollution of soil, water, and air with industrial and other waste, land degradation due to inappropriate farming practices, and extinction of life forms and threat to the planet's biodiversity with unknown environmental consequences. Many of those living in horticultural societies, who comprise the rural poor in many developing countries, are particularly vulnerable because of their limited capacity to cope with climate variability against a background of increasing global political-economic pressures, which include calls for adoption of clean energy, and often declining sustainability of livelihoods.

If changes of the magnitude predicted occur, the knock-on effects for human activities, including horticulture, are likely to be considerable, and research into these and ways to cope are seen increasingly as a priority. The 'sustainable livelihoods' approach has emerged in development contexts, which aims to approach livelihood strategies holistically, as structured around livelihood assets – comprising five types of capital (social, physical, natural, financial, and human) that are assessed according to vulnerability to shocks – which set within various socioeconomic structures and processes (government, laws, civil institutions, companies, etc.) determine livelihood outcomes (Carney, 2002). It is a flexible, propoor, people-centered approach that seeks systematically to understand livelihood strategies with a view to informing development interventions to improve the security and living standards of communities.

Key future questions are not only to what extent are variability and climatic extremes impacting on horticultural communities but also what adaptations are people currently making to cope with these and how effective are they in reducing vulnerability? It is evident that a significant part of the burden of coping with predicted environmental change will depend on the resourcefulness of communities and local means, and we need to understand the implications from their

perspective. In other words, we not only have to further understand horticultural regimes but also investigate the feasibility of people innovating on them to manage the impacts of forecast change and their possible social implications. For instance, the scope for scaling up the *baira* 'floating gardens' a half-forgotten local tradition recently seen again on the Bangladesh floodplain where climatic extremes, including floods, cyclones, heat waves, and variable rainfall, challenge millions of poor vulnerable people, trapping them in a cycle of poverty (Irfanullah et al., 2011).

The growing concern over the implications of predicted global environmental change has reinforced the rethink of priorities that occurred in the 1980s when it was realized that some small-scale subsistence focused horticultural societies were strongly resisting change as envisioned by modernization and communities were being increasingly exposed to serious perturbations beyond their control in trying to accommodate to development interventions. The 'participation' approach to development emerged as it was increasingly acknowledged that poor people need to be involved in the planning and implementation of any interventions intended to assist them. This promises to advance understanding and the interests of horticultural societies in the future, particularly with the concomitant emergence of 'indigenous knowledge' research, which represents the coming together of applied farming systems research and academic disciplines such as anthropology, geography, and ecology, which have long esteemed understanding of horticultural societies (Sillitoe et al., 2005). The assumption is that any development assistance needs to be in tune with local sociocultural and environmental contexts. It also furthers meaningful appreciation of the complex relations that inform natural resources management, as understood by local farmers, those who contend daily with them – the collapse of many interventions has been attributed to a failure to comprehend the complexity of their horticultural systems. These changes in research and development agendas bode well for the future in furthering understanding and promoting the interests of horticultural societies *along their own lines*.

Hospitals and Health: Psychosocial Aspects

Jeffrey A Alexander, School of Public Health, University of Michigan, Ann Arbor, MI, USA

Abstract

In the United States, increasingly, strong market and financial pressures are interacting with traditionally dominant institutional forces to shape the behavior of hospitals, particularly those that operate as nonprofit organizations. This situation contrasts with that of many other developed nations where hospitals and health care organizations are operated largely under public auspices. Escalating demands for greater efficiency, cost containment, and higher quality, together with counterpressures to maintain local autonomy and professional control, has resulted in both new organizational practices and organizational forms. This article describes the social forces affecting hospitals and other health care organizations, and the changes that these organizations have experienced as they attempt to accommodate potentially conflicting environmental demands.

In the United States, increasingly, strong market and financial pressures are interacting with traditionally dominant institutional forces to shape the behavior of hospitals, particularly those that operate as nonprofit organizations. This situation contrasts with that of many other developed nations where hospitals and health care organizations are operated largely under public auspices. Escalating demands for greater efficiency, cost containment, and higher quality, together with counterpressures to maintain local autonomy and professional control, has resulted in both new organizational practices and organizational forms (Guterman et al., 2010). Many of these new practices and structures are borrowed in modified form from the corporate sector. These effects are widely expressed in hospital ownership, organizational structures, and governance, as well as in work practices and controls. The most notable examples include the consolidation of hospitals into complex health systems, the consequent shift in the locus of governance away from local communities, and the increasing diversity and complexity of compensation arrangements between health care delivery organizations and physicians. Operational effects have included greater emphasis on both efficiencies in the use of human resources, increasing value in health care, and improved quality of care. Though specific environmental pressures vary in different countries, changes in the broader market and institutional contexts that hospitals face are key in understanding their evolving structure and behavior.

During the second half of the twentieth century, the dominant mode of health care delivery in the United States has evolved from individual, patient–physician relationships to care provided by organizations (Starr, 1982). At the same time, social scientists have moved from examining hospitals as closed systems, which operate independently of their environment, to seeing them as open systems, both affected by and responding to external forces such as regulation, professional norms, shifting reimbursement policies, and significant efforts to 'reforming' and aligning incentives (Scott, 1998). This perspective assumes that structural forms and organizational behavior in the health care sector are influenced by factors such as regulation, change in professional power, competition among providers, and mutualistic behavior among different types of providers. The context in which hospitals operate has been described as having two essential components: the technical environment and the institutional environment. The technical aspects of an organization's task environment involve the production of goods and services, and the market forces that reward their efficient and effective production. Institutional environments encompass the rules and requirements to which organizations must conform, if they are to receive the social and political support and legitimacy needed to survive. Increasingly, the two types of forces are seen as competing.

Organizations in the health care sector have traditionally been subject to both strong institutional and strong technical pressures. These forces have operated in separate but parallel fashion to shape the practices and structures of hospitals (Alexander and Scott, 1984). For example, hospitals traditionally maintained very loose control over physician staff as a reflection of strong professional requirements for autonomy. At the same time, they were accountable for the 'technical' quality of care through legal and quality assurance controls. Recently, market forces have played a more visible role in shaping national-policy debate concerning health care access, quality, and costs. For example, hospitals now compete actively with each other for patients and for government and health plan reimbursement that is increasingly tied to outcomes such as quality, patient satisfaction, and cost reduction. In view of this, some have argued that the influence of traditional institutional structures and practices, such as regulation, professional norms, and local control, have weakened and are now subordinated to the technical demands of the market. However, there is evidence that historical institutional forces have not been eliminated, but, instead, are interacting with the new 'market' ethos to constrain and shape the structures and practices of hospitals, including those originating in the corporate sector (Thomas and Helmreich, 2002). These interactions have given rise to a unique set of changes and practices that differ from both those common to the corporate sector and those common to hospitals in more institutionally dominant eras.

Institutional Environment of Hospitals

Institutional environments feature elaborate rules and requirements to which individual organizations must conform, if they are to receive support and legitimacy. Attention is

directed away from control and coordination of technical processes and toward conformity to externally defined requirements or regulations. The more institutionalized the environment of an organization, the more its structures and procedures are governed by external controls. This control requires specific arrangements in the organization, which are independent of contributions to technical performance (Scott, 1995). For much of the twentieth century and up until today, hospitals and other health care organizations have been subject to strong institutional pressures, including a broad array of governmental regulations and requirements and a strong ethos of local, community control. Further, numerous professional norms and prerogatives have governed what types of personnel might be hired, how tasks are distributed among them, and what procedures must be followed in performing these tasks (Nembhard et al., 2009).

The health care field in the United States has long been characterized by institutional pressures that are both strong and heterogeneous (Stevens, 1989). All branches of the federal government make decisions centrally, which affect the entire health care sector. Local and state governments also exercise authority to regulate health care. This fragmented structure of authority makes it possible for various actors to pass laws to meet particular needs, and regulations are therefore uncoordinated, at best, and inconsistent or conflicting, at worst. Further, a long tradition of volunteerism in American hospitals has complemented the inculcation of professional norms into the institutional structure of these organizations. The notions of local control, community accountability, and philanthropic support of hospitals have served to keep decision-making from becoming overly centralized. At the same time, this has discouraged the formation of a cohesive, integrated health care system.

Technical Environment of Hospitals

Notwithstanding the institutional demands on hospitals, the technical requirements of modern medicine are considerable and often require tight internal controls and careful coordination, if performance is to be effective. Hospitals have also increasingly been pressured to improve efficiency in the use of resources. Retrospective cost reimbursement was singled out as the primary explanation for both rising costs and inappropriate utilization. Critics have also identified professional specialization and hospital-based care as major contributors to rising costs. Growing specialization and fragmentation in delivery rendered services increasingly impersonal, while the predominance of inpatient services threatened accessibility and provision of comprehensive, family-oriented care.

Historically, political attention had focused on expanding access to health care, as exemplified by the passage of legislation in the 1960s extending health insurance coverage to many of the elderly (Medicare) and the poor (Medicaid). The 1980s, however, marked the beginning of a new era that shifted the focus to controlling costs (Scott et al., 2000). Several years of double-digit increases in prices threatened the economic interests of actors who paid for health care; in response, they initiated policies and practices to control costs. In 1984, the federal government's Medicare program became the first major payer to attempt to control hospital costs by paying a fixed fee for each service, rather than the 'usual and reasonable' fees that hospitals routinely charged. This key change in payment policy had significant financial and market implications for hospitals. The resulting reductions in payments to hospitals and other organizational providers cut their budgets and contributed to cash-flow problems. Hospitals and other providers tried to compensate by increasing their patient and service volume. In turn, this created more competition for patients.

A series of remedies have been proposed to deal with the cost escalation crisis. The solutions imposed have often clashed with the historical institutional functions of hospitals, namely, providing care to the community, running on a voluntary basis, and engaging in philanthropic enterprise. Direct regulatory approaches to containing costs in the 1970s have shifted to greater emphasis on legal, budgetary, and market responses to addressing these issues. Taken as a whole, these remedies fall under the general rubric of a competitive approach to controlling costs, even though, all involved substantial government oversight and occasionally intervention. Such approaches are consistent with a general societal shift toward privatization and market solutions to larger social problems. While recently court rulings have relaxed some regulations stifling collaboration among doctors and organizational providers, new regulations have reduced price-fixing and other forms of anticompetitive behavior. Together these rulings have provided both inducements and constraints on organizational behavior, such as severe limitations on hospital acquisitions and mergers.

Budgetary remedies to these conflicts have been applied at both the federal and state levels. At the federal level, the U.S. government initially budgeted a fixed reimbursement for each inpatient admission based on diagnosis. States also enacted rate-setting programs that prospectively set reimbursement levels for hospitals and other providers. These budgetary interventions have forced health care providers to attend to efficiency and have raised the level of competition among these providers. Finally, market remedies have included the introduction of the so-called 'managed care' strategies, designed to reduce utilization and thereby costs (*see* Health Insurance: Economic and Risk Aspects). Examples of these strategies have included competitive bidding and selective contracting in government programs and the use of preferred providers and risk-based financial incentives by private insurance firms. More recently, however, both state and federal governments have begun to publish information on the performance of health care providers (on both cost and quality), aimed at redressing the traditional asymmetry of information between providers and consumers of health care and have introduced new reimbursement approaches that provide incentives for hospitals and other providers to better coordinate care and reduce duplication of services (Conrad and Perry, 2009).

As expected, these interventions have lowered health care costs, decreased utilization, and, perhaps to a lesser extent, increased quality of care (Robinson, 1996; Fung et al., 2008). But there have also been other, unanticipated effects. Since the 1990s, there have been an increasing number of exits of traditional organizations from the health care system. Although most hospitals and other organizational providers that have closed have tended to be primarily inner-city and rural institutions and have done so for primarily

technical/market reasons, many others have remained operating despite financial losses and technical inefficiencies. The survival of so many marginal institutions in the face of increasing pressures from a market-based system reflects the importance of local, community support for these institutions, and the salience of legitimacy in organizational survival (Rohrer, 1989). This illustrates well the complex combination of technical and institutional forces that shape organizational life in the health care sector.

Hospital Responses to Hybrid Environments

A fundamental question becomes, how do health care organizations operating within such hybrid environments accommodate different environmental demands that are often diametrically opposed to each other? The convergence of traditional institutional and new technical forces impinging upon hospitals has created new organizational, strategic, and survival challenges for health care providers. Neo-institutional theory suggests that organizations functioning in sectors that are highly developed both institutionally and technically will develop more complex and elaborate administrative systems and will experience higher levels of internal conflict (Scott, 1995). Historically, we know this to be true for many organizations in the health care sector. Hospitals, for example, have typically operated within a dual hierarchy of control, represented on the one hand by hospital administration and on the other by hospital medical staff and physicians. These dual lines of control operate in parallel with each other, but rarely have intersected in such a way as to disrupt the relative spheres of influence over issues related to control, resource allocation, and professional prerogatives.

Conflict has been expressed in hospitals largely through increasing parity between managerial and professional logic and ideologies. The emphasis of managerial ideology on rational systems and cost-effective care has increasingly conflicted with the professional orientation toward individual doctor–patient relations and the microdelivery of specific medical services (Goodrick et al., 1997). Conflicting claims to the right way to deliver health care, the presence of alternative rationales for organizing work (professional versus managerial), and the inherent conflicts between technical and institutional pressures in the health care sector have eroded the legitimacy of hospitals. This has opened the way for a number of new organizational forms, practices, and strategies, particularly those that have symbolically represented the new ethos of privatization and corporate rationality. For example, health organizations are increasingly lobbying government and engaging in marketing campaigns in order to influence legislation and public opinion. Rather than being passive recipients of institutional changes in the broader environment, they seek actively to shape societal beliefs toward health care and the way health care is organized.

Organizational Heterogeneity

Health care delivery has been dominated traditionally by hierarchical organizations such as hospitals and health care systems. However, as competitive pressures and the demands of managing care under limited resources have increased over the past decade, a wide variety of new organizational forms have emerged. These range from managed care organizations, physician–hospital arrangements, accountable-care organizations, and physician practice management companies, to diagnosis-specific service contracts with specialized providers, such as home health care and rehabilitation firms (Iglehart, 2011).

As traditional institutional norms and practices have eroded and have been replaced by a stronger corporate rationality, we have observed greater heterogeneity among organizations in the health care sector. This new ethos suggests there is no best way to organize in order to achieve technical efficiency and positive performance in the marketplace. More variation in organizational forms is exhibited, as hospitals become less concerned with mapping the characteristics of the institutional environment onto their own structures and more concerned with achieving technical efficiencies and buffering their technical cores from environmental disturbances.

A clear response to the new market forces in health care has been the adoption of structures and practices from the corporate sector (Burns, 1990). These structures include multidivisional organizational designs, parent holding-company arrangements, contract management of facilities, and vertical integration across a number of different service lines. While these practices clearly have gained popularity during the 1990s, there is limited evidence that they actually improve the quality or lower the cost of care. Neo-institutional theorists have argued that while early adopters of these corporate structures may have done so for technical–rational reasons, later adopters may have viewed them as the prevailing institutional practices under the new market-based health care environment.

Hospital Governance

Historically, most nonprofit hospitals were overseen by autonomous governing boards composed largely of representatives of the communities the hospitals served. This type of governance arrangement reflected a longstanding institutional belief that the control of nonprofit hospitals should be vested in local communities. However, during the 1980s and 1990s, two developments have altered this traditional governance model of nonprofit hospitals, both of which are part of a larger trend toward the so-called 'corporatization' of health care. One development is the consolidation of over 40% of US hospitals into complex health care systems. In such systems, the locus of control for member hospitals is shifted to varying degrees outside local communities to system-level governing boards and corporate offices (Toomey and Toomey, 1993). Another development is corporate restructuring of hospitals, where hospital assets and decision-making authority are transferred to multiple corporate entities that may include a parent holding company and various subsidiaries. Such restructuring often entails the creation of multiple governing bodies that can attenuate the decision-making authority of the provider's community-based board.

Under a traditional model of governance, nonprofit hospitals resemble consumer cooperatives in that community representatives are in a position to determine hospital policies.

As such, a traditional form of governance is arguably a constraint on hospital price inflation, since community representatives have an incentive to resist price increases that they ultimately will incur in the form of higher insurance premiums. Also, form of governance may impact the accessibility of hospital services since a community-based board may be inclined to invest resources to expand the accessibility of hospital services to its own community (e.g., through the provision of uncompensated care). Policymakers have expressed concern that system membership and corporate restructuring are diminishing the role of communities in the control of nonprofit hospitals, and government agencies that have oversight responsibilities for nonprofit hospitals are currently examining alternatives.

Indeed, hospitals have come under increased public scrutiny for practices that appear to be inconsistent with their not-for-profit (NFP) ethos, which traditionally focuses on serving their communities in a charitable manner (Seay and Sigmond, 1989). Recent investigations into the activities of NFP hospitals have pointed to weak or lax management and governance and claim a variety of misdeeds such as excessive compensation of executives, inadequate provision of charity care, and deceptive pricing of services. These and related concerns have given rise to questions as to whether there is, in fact, sufficient difference between nonprofit and for-profit hospitals (Kane, 2007). This is another example of how hospitals are often caught between their traditional philanthropic missions and new market forces.

Physician–Organization Structures

As payment reform and competitive pressures have compelled hospitals to consolidate and provide services along a broad continuum of care, the need to integrate formerly loosely coupled elements of these organizations has increased. Perhaps, the most problematic aspect of such integration is the alignment of incentives and strategic goals between delivery organizations and physicians. Hospitals seek to engage in strategic relations with physicians in order to: (1) protect against the risks of agency from physicians who have traditionally borne little risk for the care of patients, (2) reduce transaction costs by developing economies of scale and integrating physicians into the structure of the delivery organization, (3) achieve market power both up- and downstream over suppliers and customers respectively, and (4) develop capabilities that differentiate systems from competitors in the areas of innovation, technology, and quality. While these market-driven reasons are clearly critical to hospitals and health care systems, the alignment of economic and strategic interests between organizations and physicians is difficult given the differences in cultural context, socialization, orientation to patient care, and economic incentives (Dukerich et al., 2002).

As managed care organizations and health care regulators have recognized the need to align the economic incentives of providers with the goals of cost containment and high quality, they have changed methods of provider compensation from simple discounting to risk sharing (e.g., capitation, *per diem*, or per case reimbursement for hospitals). Providers under these systems assume actuarial and utilization risk and reward. In principle, risk sharing promotes appropriate behavior, since high utilization and costs will result in deficits for either the physician group or its physicians. In practice, the physician group's form of compensation, incentives, and governance moderate these effects. For example, the incentives inherent in risk sharing can be lost if individual physician compensation is not strongly linked to holding costs below the group's fixed budget. Alternatively, if physicians feel they have no say in the formulation of incentives in compensation systems, they may be less willing to abide by them.

These examples suggest that the incentives created by risk sharing are effective only under certain conditions. Several authors have recognized that the effects of such payment mechanisms may partially depend on organizational factors such as type of governance, physician leadership, information dissemination, sanctions, and organizational culture (Kralewski et al., 2000; Alexander et al., 2000). Aside from such fundamental differences in orientation to quality and related mistrust over motives and goals, many of the problems of alignment can be traced to medical staff governance itself. In contrast to hospitals, which are organized and governed along bureaucratic lines with clearly established lines of authority and accountability, the typical hospital medical staff in the United States is organized as an association of physicians with ties to the hospital, but with little else to bind them together as a collective entity. They are essentially membership organizations that lack formal authority to impose accountability standards on their members, or to direct integrated activity with hospitals. Because of its loose structure and emphasis on individual physician interests, the association form of medical staff governance is not well suited to promote collective responsibility for patient-care quality, operational efficiency, or other areas of performance. Many states, in fact, have long had in place policies that prohibit corporations (i.e., hospitals) from employing physicians directly – the so-called 'corporate practice of medicine doctrine' – which serves to reinforce the legitimacy of the voluntary medical staff with all its previously noted difficulties (Alexander and Young, 2010).

Physicians and organizational health care providers now recognize the need to work together to manage risk and coordinate care under new reimbursement schemes. To realize these objectives, to avoid institutionalized constraints inherent in hospital–medical staff relations, and to develop the administrative infrastructure necessary for managing service delivery, many health care systems have established market-based organizational arrangements that link the delivery organization with one or more physician groups. Market-based arrangements are different from internal hospital structures in that they tend to be formally structured, contractual in character, corporate in organization, and include physicians outside the formal membership of the medical staff.

Given fundamental differences between methods of organizing by physicians and delivery organizations, however, it is highly questionable whether structural solutions to achieving greater integration between physicians and delivery organizations can be completely effective. There is only limited evidence to suggest that structural solutions work and considerably more evidence that self-selection by physicians into closely aligned structural arrangements may account for more of the explained variance in alignment than structure itself. Hospitals' attempts

to integrate and align with physicians have not always rationalized the delivery of health care, but instead in many cases have made it more complex. Physicians and their interests vary widely, and hospitals have discovered that no one structural vehicle best accommodates the interests of all physician subgroups. Consequently, it is not uncommon for multiple market-based arrangements to exist within a single organization. This makes the coordination of care and alignment of incentives at least as difficult, if not more so, as it has been under the traditional medical staff model.

Organization of Work in Hospitals

The high degree of specialization in health care means that each professional brings only a fraction of the knowledge needed to care for patients. A rich literature shows that the actions of these professionals must be well coordinated to be effective. Despite the imperative for such collaboration, effective care coordination in hospitals is often missing from professional interactions because of the hierarchical, individualistic culture of medicine (IOM, 2000, 2001), which is deeply rooted in the socialization process for health professionals and its institutionalized value system (Leape and Berwick, 2005).

Largely as a result of increasing competitive pressures and external emphases on cost containment and quality improvement (QI), the organization of work within hospitals has shifted. The reciprocal interdependence inherent in treating patients whose clinical conditions are evolving requires that care providers in the hospital setting participate in ongoing knowledge-sharing to arrive at a complete picture of the patient's situation and an effective treatment plan. Two trends are particularly in evidence: the use of teams to perform managerial and clinical work, as opposed to performing such work individually; and the use of contracts to obtain labor externally rather than to hire employees.

Because of demands by managed care firms, revised payment policies, and integrated health care systems to provide comprehensive care to patients and/or enrollees in health plans, there is growing recognition that patients need comprehensive care in order to address their multiple problems effectively. Given the broad spectrum of knowledge necessary for comprehensive care, there is growing belief that teams of practitioners with complementary roles and skills are best suited to providing high quality, cost-effective patient care (Fried and Rundall, 1994). Teamwork in the clinical round is also perceived as an antidote to fragmentation in services, a traditional problem in health care delivery. For example, repeated patient assessments by various health care providers add unnecessary costs to patient care, when one combined assessment would suffice. Advocates of team-oriented care cite studies that consistently show that collaboration among physicians, nurses, and other health care personnel enhances the quality of care and patient satisfaction (Nikolaus et al., 1999; Le et al., 1998).

Team-based care stands in marked contrast to the traditional hierarchical work relations in most hospitals, which accord the physician a role of absolute autonomy and control over patient-care processes. The growing emphasis on prevention, wellness, and cost-effectiveness in care delivery make this hierarchical structure outmoded. Flatter structures and more collegial relations among providers appear to be the developing norm. For example, many nurses advocate a collaborative relationship with physicians where nurses have primary responsibility for health maintenance, prevention, and diagnosis and treatment of routine cases, while physicians retain responsibility for the diagnosis and treatment of complex cases and the prescription of medications.

Contracting for labor services, as an alternative to employment, stems from the need for more flexibility in an increasingly competitive environment. Hospitals need to be able to make rapid changes in their workforce in response to demands from a volatile market. Rather than staffing to accommodate periods of peak demand with attendant downtime for slack periods, hospitals have increasingly adopted a contingent approach to staffing, responding to the particular needs of the organization at a given time (Katzman, 1999; Rizzuto et al., 1999). Contracting typically occurs in housekeeping, business, and clinical services. Proponents argue that contracting frees top managers to concentrate on core services, brings specialized expertise to the organization, improves flexibility through the ability to terminate contracts, reduces supply costs through superior purchasing power, and promotes the recruitment of specialists who may be in short supply. Critics argue, however, that the contract-management firm and the contracting organization may fail to clarify performance goals or that contracted staff may have difficulty working with other departments and full-time personnel. Perhaps most importantly, some believe that contracting for a wide variety of services without a clear strategy risks damaging organizational coherence and control (D'Aunno et al., 1996).

Quality of Care in Hospitals

Another illustration of the organizational response to technical and institutional pressures lies in the area of health care quality (McGlynn et al., 2003). On the one hand, decline in public support and trust for hospitals has reduced their impetus to assure quality and discipline members of their organizations for lapses in quality. Responsibility for quality has begun to shift to the payers of health care and their agents (e.g., managed care organizations), as well as to the courts, which adjudicate an increasing number of malpractice suits against hospitals and physicians. These trends reflect a growing tendency to think of health care as a commodity rather than an entrusted service provided by professionals and professional organizations. On the other hand, there is greater emphasis placed on QI systems within organizations as a counterbalance to external controls over quality and as a response to market pressures to increase the efficiency and effectiveness with which care is delivered (Kimberly and Minvielle, 2000). Again, this duality of external versus internal control is a juxtaposition based in the competing demands placed on hospitals by institutional and technical forces.

Hospitals, in particular, are being challenged by increasingly competitive markets and regulatory changes to produce high quality care without raising costs. Given the multiple pressures and problems associated with health care quality, hospitals face the additional challenge of developing policies, procedures, and

incentives to improve quality within a domain that has traditionally been the province of highly autonomous professionals. QI practices have emerged in recent years partially as an alternative to quality assurance and as a reaction to the shortcomings of outcome-based control (McLaughlin and Kaluzny, 2006). With mounting pressure to maintain or improve quality in the face of reduced resources, hospitals have begun to look to process improvements as a mechanism to provide high quality care, while containing health care costs. While the adoption of QI appears to be an internally generated response to changing market conditions, for the most part, accrediting bodies such as the Joint Commission on Accreditation of Health care Organizations have also encouraged hospitals to adopt QI.

Given the traditional emphasis on provider–patient relations, individualized approaches to improving quality have received the vast majority of attention to date. Although the knowledge and practices of individual physicians are important for high quality care, increasingly clinicians practice within groups or systems of care. As such, the quality of care delivered depends critically on the ability of these groups or systems to prevent errors, coordinate care among settings and practitioners, and ensure that relevant, accurate information is available when needed.

One of the most promising recent developments is the effort to institutionalize QI in hospitals as a coordinated, organization-wide approach to care strategies (Berwick et al., 1990; Gaucher and Coffey, 1993; Carman et al., 1996). These practices, collectively, are designed to systematically examine and improve processes of care and care support in organizational settings. Typically, these QI efforts are strongly rooted in evidence-based procedures and rely extensively on data collected from hospitals about care processes and patient outcomes.

However, while few would dispute the importance of providing high quality care in hospitals, many hospital managers feel that they cannot afford to invest heavily in QI programs because such investments would erode their bottom line and make them less competitive in markets where cost containment receives primary emphasis. By contrast, proponents of investing in QI efforts maintain that enhancing quality makes the hospital more attractive to patients, physicians, and payers, thereby contributing positively to the hospital's financial health. Although this issue has been widely debated in terms of 'the business case for quality,' the absence of empirical research in the area has opened the debate to competing technical and institutional beliefs rooted in the competing values of professionalism, market competition, and community control (Hendricks and Singhal, 2001; Ittner and Larcker, 1996; Lederer and Rhee, 1995).

Hospital Behavior in Other Nations

The focus of this article has been to associate change in hospital structure and behavior to change in the broader market and institutional contexts in which these organizations operate. The United States has been prominently featured in this discussion because of the somewhat unusual combination of strong technical and institutional pressures to which hospitals must respond. Other countries, however, may diverge markedly in the degree to which either institutional or market forces play a role in shaping hospital behavior. For example, in countries where health care delivery is highly centralized and funded exclusively by the government, one would expect to find much more structural homogeneity among hospitals, in marked contrast to the increasing diversity and differentiation among US hospitals. In other nations, where privatization and multiple sources of health care funding predominate, hospitals are more likely to resemble in their structure and behavior of other commercial vendors of services to the market.

Recent trends in OECD countries would seem to indicate that they are facing technical pressures for increased efficiency similar to those in the United States (Normand, 1993). Significant reductions both in the number of hospital beds per 1000 and in average length of hospital stay have resulted, particularly in Scandinavian countries. In the countries of the former Soviet Union, on the other hand, average length of stay has not dropped, despite mounting financial strain due to economic instability. One potential explanation for this is lingering institutional norms regarding appropriate clinical practice (Hensher et al., 1999). This may illustrate how specific institutional beliefs about health and health care in a given nation may shape hospital behavior in ways that differ substantively from the ways in which institutional forces shape hospital behavior in the United States. For example, in Taiwan, the deeply seated belief that family is the primary care giver is reflected in the hospital practices of incorporating family members in patient education, extended visiting hours, and even boarding with the patient during the hospital stay. Cross-national differences in hospital structure and behavior are thus likely to be a reflection of both the structure and content of the broader environment from which hospitals obtain patients, critical resources, and legitimacy.

Abstract

Harold Hotelling (1895–1973) was an internationally renowned American leader in developing the intellectual foundations of statistics, and in furthering areas of mathematical economics. His best known statistical research concerns multivariate analysis, where he introduced Hotelling's T^2, principal components analysis and canonical correlations analysis. Hotelling's T^2 is a multivariate generalization of Student's *t*-test, principal components are uncorrelated linear combinations of the underlying data capturing the data's variability, and canonical variables and correlations help to simplify the dependence relationships between two sets of multivariate measurements. Hotelling's major contributions to mathematical economics concern natural resource economics, spatial economic competition, and welfare economics. Hotelling additionally played a prominent role in the administration of statistics in universities and national societies.

Harold Hotelling (1895–1973) was one of a handful of statistical researchers who in the first half of the twentieth century developed the solid intellectual foundations of the then newly developing discipline of statistics. In addition, he was also an important contributor to several areas of mathematical economics. His academic career includes: professorships at Stanford University, Columbia University, and the University of North Carolina at Chapel Hill, and his professional leadership involved major statistical and economic societies. He is perhaps best known for his statistical work in multivariate analysis, introducing the concepts of principal components, canonical correlations and Hotelling's-T^2. In mathematical economics, he contributed to natural resource economics, spatial economic competition, and introduced the welfare equilibrium proposition.

Early Life

Born on 29 September 1895 in Fulda, Minnesota, Harold Hotelling, whose parents were Clair Hotelling and Lucy Rawson, was the oldest of six children. Having moved with his family to Seattle at age nine, Hotelling studied journalism at the University of Washington, taking time from his studies to work on a weekly paper. In 1919, he received his BA in Journalism, graduating Phi Beta Kappa. Encouraged, in part, by the mathematician and well-known historian, Eric Temple Bell, he went on to graduate study in mathematics at the University of Washington, receiving an MA in 1921. It was during this time that he married Floy Tracy in 1920. He received his Ph.D. in Mathematics in 1924 from Princeton University, doing dissertation research on dynamic topology with Oswald Veblen, although his original intent was to study mathematical economics. His interest in economics took root while growing up and in his belief in 'the importance ... of a study of economics [in] that [it] might possibly impress some people to the point of making some changes in the institutions with which they had become familiar [and] which I [Hotelling] was already prepared to condemn vigorously.' Alternatively, he 'couldn't escape the lure of mathematics' and notes that he 'hoped and [it] appeared that the mathematics would be extremely prolific of new economic theorems and ideas if followed out' (Hotelling, 1963).

Beginning at Stanford University

Invited to join the Food Research Institute at Stanford University, Hotelling was a research associate there from 1924 to 1927, following which he was an associate professor in Stanford's Department of Mathematics (1927–31). An early indication of the breadth of his intellectual interests is illustrated by the fact that in 1927 he taught courses on mathematical statistics, differential geometry, and analysis situs (a forerunner of topology), and in that year published papers on the application of the latter to statistics, and on differential equations subject to error. While working in the Food Research Institute, he was introduced to the work of R. A. Fisher (five years his elder), and through their mutual correspondence they became friends. In fact, Hotelling wrote the book review in the *Journal of the American Statistical Association* (Hotelling, 1927) of the first edition of Fisher's *Statistical Methods for Research Workers* (and also did subsequent reviews there of the Second through Seventh Edns.). After the planned visit of Fisher to Stanford in the summer of 1928 was abandoned, Hotelling visited Fisher at the Rothamsted Experimental Station during the second half of 1929. Their connections continued and at the outbreak of World War II, Hotelling, along with three others, wrote to Fisher volunteering to care for Fishers' six daughters in the United States during the war. However, a last minute cancellation kept the Fisher children in Britain (Box, 1978: p. 377).

While at Stanford, Hotelling wrote a number of path-breaking papers in statistics and in mathematical economics. The most notable among these statistical results was his generalization of Student's *t*-ratio to handle multivariate response data (Hotelling, 1931). This generalization remains known as Hotelling T^2. His paper with Holbrook Working (Working and Hotelling, 1929) on modeling and linear prediction first demonstrated that the standard error of the estimate of a linear regression depended on the independent variable's value, thereby giving rise to the well-known

Working–Hotelling curved simultaneous confidence regions for a linear regression. His research contributions to mathematical economics were equally notable. His 1929 paper provided a game-theoretic solution given by two differential equations to a problem of price and location competition between two entities in a spatial setting. His 1931 paper on the economics of exhaustible resources is recognized as the seminal paper in the field of natural resource economics. In that paper, Hotelling demonstrates that in an equilibrium setting, prices of exhaustible natural resources will tend to rise over time at a percentage rate equaling the interest rate.

Columbia University and the Statistical Research Group

Hotelling moved to Columbia University in 1931 as a Professor of Economics, having been recruited to further the development of mathematical economics, and also to initiate mathematical statistics. Throughout his career at Columbia and later at the University of North Carolina at Chapel Hill, Hotelling was superlative at both attracting outstanding researchers and mentoring young researchers destined for stardom. The Nobel-prize winning economist, Milton Friedman, was among the earliest mentored by Hotelling, spending 1933–34 at Columbia learning mathematical economics from him. Later mentoring Kenneth Arrow, another Nobel-prize winning economist, Hotelling was also instrumental in attracting Abraham Wald, W. Allen Wallis, and Jacob Wolfowitz to the statistics facility at Columbia. As a teacher, Hotelling was perceived to be organized and comprehensive, interweaving theory with application. Importantly, an appreciation of research was imparted to his students, and he was able at an interpersonal level to instill in his students their own confidence to be successful at research (Madow, 1960).

Hotelling was one of three original voting fellows of the Institute of Mathematical Statistics on 12 September 1935, and was President of that Institute in 1941. He began his association with the Cowles Commission, participating in its first Summer conference in 1935, and served as President of the Econometric Society during 1936–37. In 1939–40, he was a Visiting Lecturer at the Indian Statistical Institute and was President of the Indian Statistical Congress (1940).

Along with Wallis and Wolfowitz, Hotelling was a charter member of the Statistical Research Group (SRG), at Columbia, for which Wallis was appointed Director of Research. The SRG, founded on 1 July 1942, and in existence until September 30, 1945, was an extraordinary research group of statisticians whose goals were to provide research support and analyses for the armed forces in furthering the quality and accuracy of their war efforts. The origins of sequential analysis stem from Wald's work for the SRG, and among Hotelling's contributions were techniques for control charts for multivariate data (Kruskal, 1980). (A detailed history of the SRG is provided by Wallis, 1980).

Early in Hotelling's career at Columbia, his wife, Floy, died in 1932, leaving behind two small children. In 1934, Hotelling married Susanna Edmundson and together they had six children, five sons and a daughter (who died in her infancy).

Hotelling, during his prewar years at Columbia, continued to produce ground-breaking research in statistics and economics. His 1933 and 1936 papers introduced and lay the groundwork for principal component analysis as a multivariate statistical technique for simplifying the structure of large numbers of correlated measures (Hotelling, 1933, 1936a). In 1936, he extended notions of multiple correlation to canonical correlations in order to measure and study the relationships between two dependent sets of correlated responses (Hotelling, 1936b). In the field of economics, his 1935 paper provided a consistent theory uniting demand and utility by means of a constrained optimization problem and his presidential address to the Econometric Society in 1938 (Hotelling, 1938) introduced a welfare equilibrium proposition which leads in certain societal settings to the argument that goods be priced at their marginal costs. In 1940, his innovative and insightful paper on the teaching of statistics in universities was published (Hotelling, 1940). In this prescient paper, Hotelling observes the inevitability of the increased demand for statisticians, and argues that the teaching of statistics in universities would be best done solely by statisticians in separate departments of statistics (a quite novel idea in 1940!). With regard to this article, Jerzy Neyman (1960) later wrote 'in my opinion the establishment of the excellent departments of statistics in such universities as Chicago, Columbia, Harvard, North Carolina, and Stanford is due to a considerable extent to the publication of Hotelling's article.'

Career at University of North Carolina

After the war in 1946, Hotelling was recruited by Frank Graham, President of the University of North Carolina at Chapel Hill to start the Department of Mathematical Statistics there upon his arrival. In addition to being appointed professor of mathematical statistics and professor of economics, he was named Associate Director of the Institute of Statistics (directed by Gertrude Cox), which was constituted with Chapel Hill's department and the Department of Experimental Statistics at North Carolina State, as well as related groups in psychometrics, social sciences and biostatistics. It is notable that when Hotelling was planning to go to Chapel Hill, he proposed that Wald join him there. In order to entice Wald to remain at Columbia, a Department of Mathematical Statistics was promptly proposed and officially approved in December 1946 (Hoxie, 1955). As at Columbia, Hotelling attracted outstanding statisticians to the Chapel Hill faculty including R. C. Bose, Wassily Hoeffding, P. L. Hsu (who had been at Columbia with Hotelling), William Madow, Herbert Robbins, S. N. Roy, and Walter Smith. Hotelling relinquished the chairmanship to George Nicholson in 1952, and devoted the remainder of his career there to his research and his students.

His research at North Carolina involved, on the whole, elaborations and in-depth further study of some of his earlier research. Noteworthy among these is his work in 1947 and 1951 on hypothesis tests related to multivariate analysis of variance, which lead to the testing criterion referred to as the Lawley–Hotelling trace. He formally retired in 1966, but continued to be active in the department. He was elected to the

National Academy of Sciences in 1970, and received a number of other academic honors during this period. Subsequent to a serious stroke in mid-1972, Harold Hotelling died in Chapel Hill, North Carolina on 26 December 1973.

Hotelling's Contribution to Multivariate Statistical Analysis

One of the origins of statistical hypothesis testing is a test that the mean μ of a normal distribution has a specified value μ_0. The resultant Student's t-test, obtained in 1908, remains as one of the most used statistical procedures. The t-statistic is

$$t = \sqrt{N(\bar{x} - \mu_0)/s}$$

where $\bar{x}$ and s, respectively, represent the mean and standard deviation of a sample of size N. Hotelling recognized that many experiments will have correlated measures $x_1, \ldots, x_{,p}$ which arise from a multivariate normal distribution, and he provided the Hotelling's T^2 test to handle the means of multiple measurements (Hotelling, 1931). For a sample of size N let $\bar{x} = (\bar{x}_1, \ldots, \bar{x}_p)$ denote the sample mean vector and $S = (s_{ij})$ represent the sample covariance matrix.

The T^2-statistic is

$$T^2 = N(\bar{x} - \mu_0)S^{-1}(\bar{x} - \mu_0)'$$

where $\mu_0 = (\mu_{10}, \ldots, \mu_{p0})$ is the specified mean vector in the hypothesis. When the hypothesis is true, $(N-p)T^2/p(N-1)$ has an F-distribution with p and $N-p$ degrees of freedom.

Analogous to Student's t-test, the T^2-statistic can also be used to test for the equality of the mean vectors of two normal distributions that have the same unknown covariance matrix but unequal means, μ and ν. Now the statistic becomes

$$T^2 = \frac{N_1 N_2}{N_1 + N_2}(\bar{x} - \bar{y})S^{-1}(\bar{x} - \bar{y})'$$

where $\bar{x}$ and $\bar{y}$ are mean vectors from samples of size N_1 and N_2, respectively, and S represents the pooled sample covariance matrix. Although there are many parameters in this model, under the null hypothesis the distribution of $(N_1 + N_2 - p - 1)$ T^2/p has an F-distribution with p and $N1 + N_2 - p - 1$ d.f.

The T^2-statistic additionally arises as a linear discriminant, as noted by Fisher, and is the sample analog of the Mahalanobis squared distance.

Quite remarkably, Hotelling noted that for the two-sample problem, the T^2 statistic is invariant under the transformation $\bar{x} \to \bar{x}A$, $\bar{y} \to \bar{y}A$, where A is any nonsingular matrix. This anticipated a general theory of statistical invariance developed much later. In particular, the T^2-test has a number of optimal properties among invariant tests: (a) the T^2-statistic is the only invariant function of the sufficient statistics $\bar{x}$ and S; (b) as a test statistic it is the uniformly most powerful test among all invariant tests; and (c) the noncentral distribution depends on the scalar parameter $(\mu - \nu)\sum^{-1}(\mu - \nu)'$, which is the only invariant of the parameters.

Large data sets either in exploratory data analysis, data mining, or model building are accompanied by a large number of variables. The reduction of numbers of variables is often a first step in trying to uncover patterns in the data. Because multivariate measures $x_1, \ldots, x_p$ are related, there is the need to disentangle the correlational structure. To accomplish this, Hotelling (1933, 1936a) introduced the p principal components $z_1, \ldots, z_p$, which are linear combinations of the underlying measures, namely $z_k = \sum_{j=1}^{p} a_{ki}x_i$, $k = 1, \ldots, p$,where the coefficients are normalized by $\sum_{i=1}^{p} a_{ki}^2 = 1$. The first set of coefficients $a_{11}, \ldots, a_{1p}$ is chosen so as to maximize the variance of z_1. The second set of coefficients $a_{21} \ldots, a_{2p}$ is chosen to maximize the variance of z_2 subject to the constraint that z_1 and z_2 are uncorrelated. At each step the variance is maximized, but with the additional constraints that each z_k be uncorrelated with $z_1, \ldots, z_{k-1}$. Their ordered variances Var $(z_1) \geq \ldots \geq$ Var (z_p) turn out to be the characteristic roots of the population covariance matrix.

In effect, principal components provide transformed coordinates that are uncorrelated, thereby disentangling the measures. Because the principal components are ordered according to their variances, this permits the researcher to focus on a subset of principal components that contributes substantially to the total variance. In multiple regression, the predictor variables often are closely related, and the problem of multicollinearity results. Principal components is one important procedure that introduces orthogonality and reduces dimensionality, thus removing multi-collinearity.

To build a hierarchy of correlational measures one can start with the ordinary Pearson product moment correlation between x and y. With multiple measures $x_1, \ldots, x_p$ and y one generates the multiple correlation of y anclthe linear combination $y^* \equiv \sum a_i x_i$, which is the maximum correlation between y and y^*. Suppose now there are multiple measures $x_1, \ldots, x_p$ and $y_1, \ldots, y_q$. To analyze the relation between these two sets of variates, Hotelling (1936b) defined canonical correlations between u_k and v_k, which are the correlations of linear combinations $u_k = \sum a_{kj} x_j$ and $v_k = \sum b_{kj} y_j$ where $k = 1, 2, \ldots, K \equiv \min(p, q)$. The coefficients are normalized so that the variances of u_k and v_k are 1, and are chosen so as to maximize the correlations, and such that $u_1, \ldots, u_k$ are mutually uncorrelated and $v_1, \ldots, v_k$ are mutually uncorrelated $k = 1, \ldots, K$. The new variables u_k and v_k, $k = 1, \ldots, k$ are called the canonical variables; furthermore, it turns out that u_i and $v_j (i \neq j)$ are uncorrelated. The discovery of the corresponding matrix factorization is quite remarkable. A special case of this factorization leads to the singular value decomposition, which is a very important representation in numerical linear algebra.

As a result of this decomposition, one can transform the original variables to new coordinates $(u_1, v_1), \ldots, (u_K, v_K)$, that exhibit a simple structure: (1) the pairs are uncorrelated; (2) the pairs are ordered decreasingly in accordance to their correlations (which are non-negative); that is, (u_1, v_1) are maximally correlated; and (3) the variances of the u_k's and v_k's are normalized to be one. In a 1935 paper, Hotelling had earlier focused on the first pair (u_1, v_1), and he called u_1 the most predictable criterion and v_1 the best predictor.

Principal components and canonical correlations can be viewed in terms of roots of a determinantal equation and estimated from their sample analogues. It was this context that opened an entire area of statistical research on the distribution of the roots of random determinantal equations. In 1939, a number of papers appeared simultaneously in the statistical literature in which the central distribution of the roots were

obtained. From then until the present, there is a continuing flow of theory concerning the noncentral distributions of roots of sample determinantal equations.

Hotelling's training as a mathematician provided him with a warehouse of tools that he applied to statistical problems. Among his first papers was a presentation in 1926 to the American Mathematical Society on the use of topological principles in the derivation of distributions. Many of his later results were obtained with geometrical arguments. He was able to exploit asymptotic theory to obtain normal approximations and limiting results. Hotelling, in 1930, was the first to attempt to state precise conditions for the consistency and asymptotic normality of the maximum likelihood estimator. With Lester Frankel in 1938, he obtained expansions for the distribution of Student's *t*-statistic, thereby leading to a useful normal approximation.

With his interest in relations between variables, Hotelling recognized that the required normality assumptions may be unrealistic. This led him to study the nonparametric version of the product moment correlation. Together with Margaret Pabst, Hotelling studied the Spearman rank correlation coefficient and they showed that for large samples it approximately follows a normal distribution. In 1953, Hotelling continued his analysis of correlations and obtained expansions of Fisher's *z*-transformation of Pearson's product moment correlation. This work remains among the definitive results in this area.

Hotelling wrote on matrix calculations and developed methods that still stand. His work on weighing designs led to a number of combinatorial generalizations. Although Hotelling had a mathematical focus for his research, he was not averse to working on applied problems. The range of his applied papers include results concerning the physical state of protoplasm, duration of pregnancy, causes of birth rate fluctuations, anthropomorphic measures of Southwest Indians, and effects of pregnancy on dental caries.

Harold Hotelling's originality and imagination is seen in both the genius of his research that produced innovative methods that stimulated whole areas of modern statistics and in his prescient leadership in the discipline of statistics. Further details concerning Hotelling, including his complete bibliography, can be found in Olkin *et al.* (1960), in Pfouts (1960), and in three articles appearing as 'Three papers in honor of Harold Hotelling at 65' in *The American Statistician* **(14),** published in 1960 (pp. 15–25).

Abstract

Household archaeology developed in the 1980s as a reaction to the dominant regional scale of traditional ecological–evolutionary models in archaeology by focusing on the study of intrasettlement relations. The first household archaeology studies were designed to provide detailed microscale analysis of demographic, social and economic processes of evolutionary change. These studies focused on what households do, rather than what their social form is. The initial impetus for household archaeology came from archaeologists who were excavating well-preserved architectural remains in Mesoamerica, the southwest US and in Europe. Household archaeology studies were enriched by models (mostly Marxian) that emphasized the role of dominance structures and social inequality within and between households in larger socioeconomic transformations. Archaeological evidence of the spatial differentiation of domestic production and its architectural context became the heart of these household archaeology studies. In the late 1990s household archaeology transformed into a number of strands that embraced the post-processual critique in archaeology, recognizing the historical contingency of the social practice of individuals in the household and their role as the foundation of larger social transformations, and the active role of materials use spaced en rules throughout including houses – in creating and maintaining the world of these household actors. This theme has continued into the twenty-first century.

Introduction: The Emergence of Household Archaeology

Household archaeology emerged in the late 1970s and early 1980s as a late development of social archaeology on both sides of the Atlantic. The aim of household archaeology is to create a context in which a humanized reconstruction of the past may be nurtured, through the study of intrasettlement relations. Such an investigation at the microscale involves the intensive recording of archaeological observations and detailed excavation of an area broad enough to include architectural and other features of the built environment. The criticism of such an effort is that it produces an isolated picture of one part of a social group – perhaps only one household – that does not provide a statistically valid extrapolation to the rest of a settlement, or from one settlement to the regional scale.

Household archaeology developed both as an extension of and a reaction, by both processual ('new') and Marxist-oriented archaeologists to the social evolutionary features of social archaeology (Robin, 2013). Social archaeology provided data and inferences for explanations of change and variation of past cultural systems, focusing on intersettlement relations, especially in terms of the interaction of political leaders on a regional basis within the parameters of ecological features such as distance and resource distribution. Marxist-oriented studies added the dimensions of ideology and power relations in production and distribution.

A criticism of the macroscale models of social change has been that, in identifying the longer-term evolutionary trajectory of, for example, resource control, hierarchical social relations, and population growth, and in establishing the general social form of a group, the context of shorter term changes and variability is given a lower priority in explanation. In this way a dehumanization of the past has been created in order to 'write history (or prehistory) large.'

Household archaeology developed in the 1980s and 1990s as the result of a growing interest in intrasettlement relations, but it is a sub-discipline that is neither unified, organized, nor recognized within archaeology. The aims and agendas of the archaeologists who carry out studies that are termed 'household archaeology' are as variable as are the theoretical strands of archaeology itself.

Household Archaeology: Archaeology at a Small Scale

When it was initially developed in the late 1970s the study of households aimed at filling in the most detailed level of settlement pattern and activity analysis, which could then be extrapolated to make more general statements about demographic trends, specialized production, class structures and so on (Flannery, 1976). Later, in the important volumes edited by Wilk and Rathje and Wilk and Ashmore, the importance of households as 'fundamental elements of human society' was emphasized (Ashmore and Wilk, 1988, p. 1; Wilk and Rathje, 1982). At this time it was suggested that, since households are the level at which social groups articulate directly with economic and ecological processes, their study would offer a chance for archaeologists to examine social adaptation (in a functionalist sense) with direct reference to the empirical details of the archaeological record. It was assumed this would be done within the methodological framework of scientific logical positivism. In other words, household analysis would allow archaeologists to 'bridge the existing 'mid-level theory gap' in archaeology' (Wilk and Rathje, 1982, p. 617). Thus household archaeology developed alongside the empirical theory-building in archaeology, known also as middle range research, that lies at the heart of the history of processual archaeology at the end of the twentieth century (Smith, 2011).

It is clear that household archaeology in the 1980s implied examining and analyzing social change at a microscale as a complement to analyses of social and economic change at a broader scale of regions and continents. Household archaeology served to provide a richness of detail, but was not an end in itself. The ultimate target was to understand social evolutionary change.

Sources of Inspiration for Household Archaeology

The explicit inspiration for household archaeology comprised the studies of households and multiscalar histories written by historians (including historians of the so-called Annales school) (Braudel, 1972), and by anthropologists, especially those interested in historical demography and historical anthropology (Arnould and Netting, 1982; Laslett and Wall, 1972; Netting et al., 1984), (Hammel and Laslett, 1974, p. 76). It is the latter who coined the term 'co-resident domestic group,' as a way to bring together the enormous diversity of the minimal social group – family, household, housefuland to use a term that was not subject to 'cultural bias' and would have value for 'objective scientific analysis.' The '"co-resident domestic group" consists of those who share the same physical space for the purpose of eating, sleeping and taking rest and leisure, growing up, childrearing and procreating' (Hammel and Laslett, 1974, p. 76).

Archaeologists envied the historians and social anthropologists their knowledge about the kinship relations and the demographic composition of the members of a domestic group that allowed them to explore the 'co-resident domestic group' in terms of variability in their size and kinship composition, and the cooperative activities of their members (Smith, 2012). Traditional scientific archaeological methodology puts limitations on the investigation of the social composition of or relations within the domestic group. In view of the dangers inherent in using architectural features or any other archaeological data to identify a 'household' on a prehistoric site, Wilk and Rathje pointed out that it was more productive for archaeologists to investigate questions such as what co-residents of a domestic group (households) do, rather than what their social form is (who lives there and how they are related) (Wilk and Rathje, 1982). Thus, for example, it was argued that to understand transformations in the social relations of production in Neolithic Southeast Europe, it was not essential to be able to identify 'households' in the historical and anthropological sense of the term (Tringham, 1990, p. 603). It was sufficient to be able to investigate changes in co-residence and the cooperative activities of kin-based co-resident domestic groups.

It is not surprising that the impetus for household archaeology came from archaeologists who had focused on the excavation and interpretation of well-preserved architectural remains. Architecture – more broadly, the built environment – provides the essential context of co-resident domestic groups. Archaeologists working in prehistoric Mesoamerica led the field (Ashmore and Wilk, 1988; Wilk and Rathje, 1982; Yaeger, 2013). Simultaneous and parallel developments were occurring in the Southwest US with archaeologists working with spectacular Pueblo architecture, such as Grasshopper Pueblo (Ciolek-Torrello, 1986; Riggs, 2007), and in Europe and the Near East with archaeologists working in Neolithic architectural contexts (Bogucki, 1988; Tringham, 1990, 1991). The Chacmool conference on Household and Community provided a welcome synthesis of the diverse routes to household archaeology in place by 1989 (MacEachern et al., 1989).

Modeling Household Activities in Archaeology

In modeling the economic and social role of co-resident domestic groups, participants of 'household archaeology' have followed social anthropologists in their models of the domestic mode of production (Chayanov, 1966 (reprinted 1986), Netting et al., 1984; Sahlins, 1972). These models characterized self-sustaining agriculturists and horticulturists who live in permanent villages and carry out relatively small-scale production (Isendahl and Smith, 2013). Such studies have emphasized the importance of the function of households as the organizing units of cooperative labor, production, consumption and sharing of resources, the transmission of property and rights from one generation to another, and the creation and maintenance of ties and alliances with other units through marriage and other forms of exchange. These same essential features of social reproduction became the objects of investigation of household archaeology (Ashmore and Wilk, 1988; Wilk and Rathje, 1982).

The study of 'what households do' has been enriched by the Marxist focus on ideology, power and social inequality. In the domestic mode of production the pattern of domination and inequality between and within different households of a settlement and between different settlements, although temporary and flexible, is thought to comprise a crucial variable in stimulating and enabling larger-scale transformations such as the intensification of production, the increase of the labor supply, and the increase in cultural complexity (Meillassoux, 1978).

Inequalities certainly exist, along with innumerable variations, between households and are the result of differences in the cycles of demographic and economic evolution through which households pass – cycles in which they expand, accumulating wealth, power, property, and members, and then contract (Cuellar, 2013). Thus, at any one time the households of a settlement will demonstrate differences in membership, the composition of the labor force, and the structure of dominance within the co-resident group and within the settlement as a whole. They will demonstrate differences in relations with groups outside the village, and, most importantly, differences in access to the products and processes of production. This concept of small-scale social inequality is the basis of a number of archaeological models that use the emerging importance of households as the unit of social reproduction to explain larger social and economic transformations (Rathje and McGuire, 1982; Tringham, 1990).

These differential patterns of social and economic relations reflecting social inequalities, however, have such a low archaeological visibility that these societies have traditionally been regarded as 'egalitarian.' The difficulty in recognizing inequality in 'egalitarian' societies is due to the fact that it is ephemeral and not cumulative. An additional significant factor, however,

is that inequality in such societies is not based on such criteria as the ownership of land and other material property, which are easily definable or easily recognizable in the archaeological data (Price and Feinman, 1995). Control of labor – not land, capital or property ownership – is the crucial variable on which inequality is based in precapitalist self-sustaining societies. Thus, those who control the circulation of labor and its products, control the social reproduction of society. At the scale of the domestic unit or household, this may be an individual within the household, or it may be 'senior' households who control the labor of 'junior' households. It has been argued that inequality at this scale creates tensions in numerous spheres and is a crucial variable in the process of socioeconomic transformation that can be observed in the archaeological record (Tringham, 1990, p. 608).

Archaeological Evidence of Household Inequality

The primary requirement for the examination of the social context of production and economic life at an archaeological site (in other words, of household archaeology) is that a number of domestic architectural units be exposed by excavation. This will enable a comparative view of co-resident domestic groups across the settlement at any one time. This information is enhanced by the provision of such a picture through time. Only when a large number of domestic structures is exposed is it possible to tell whether, for example, all the structures in a given excavated occupation horizon represent residences or parts of residences; whether the differentiated units of co-residence can also be differentiated as units of cooperative production; whether all the domestic structures were occupied at the same time; whether they all became part of the archaeological record at the same time or whether they were destroyed or abandoned at different times, and, finally whether they appear to be in a parallel stage of their use-lives at the time of destruction or abandonment or whether some seem to have been more recently established than others (Paynter, 1989). The study of archaeological architecture in terms of the use-life of the buildings has greatly enhanced these efforts for the purposes of household archaeology (Tringham, 1994). In this way the context and nature of the construction, maintenance, occupation, modification, and abandonment/destruction, and replacement of a residence all become objects of knowledge. Traditionally, they would have comprised elements that were subsumed under the formal features of the building. The investigation of a building through different stages of its use-life, brings to light many important aspects that would otherwise have been ignored; for example, modifications such as the addition or removal of rooms during the cycle of growth and decline of a domestic unit; efforts to prolong the use-life of a building by repairs and renewals; symbolic emphasis placed on particular use-life stages such as re-plastering, the destruction of old houses (for example by fire), or founding of new houses (Tringham, 1994).

Inequalities within and between domestic units are manifested archaeologically by the spatial differentiation of the production process (that is, in the production, consumption, and distribution of food and nonfood resources) (Wright, 2014). In each case the pattern of economic activity (and inequality) should have a distinctive appearance, demonstrating differential access to the materials, means, process, and products of production. The expectation is that different households will show differential access not only to the products of exchange with other groups but also to the raw materials, techniques, and equipment for making use of resources, such as food items, minerals, and ceramics. Such a differentiation of economic activity is frequently, but not necessarily, accompanied by specific styles of material elaboration, such as ceramic decoration.

Trends in Household Archaeology

For many years household archaeology remained marginal to the mainstream of processual (new) archaeology. In his review of Ashmore and Wilk's edited volume on Household Archaeology in Mesoamerica, David Freidel noted that for the interest in and impact of 'household archaeology' to be sustained, it would need to be incorporated into a more ambitious theoretical program in archaeology (Freidel, 1989). Its incorporation into Marxist models of power and social inequality certainly helped in this respect. The theoretical basis that has contributed most to sustaining interest in household archaeology, however, has been that of feminist anthropology and theories of social practice (Bourdieu, 1977; Moore, 1988). A common theme of these diverse poststructural theories has been their development beyond neo-Marxian models of power and labor control to models of how ideologies of gender, class, labor, production, identity, etc., are constructed, maintained and transformed. They focus on domestic arenas and the contexts of daily practice as being the most significant places where these negotiations between social agents take place. During the later 1990s these models came to characterize the many faces of post-processual archaeology, one of which is an archaeology of households that has transformed into an archaeology of gendered places (Tringham, 1994).

In the archaeology of gendered places, the archaeological record is not only analyzed and observed at a microscale, but also interpreted at a microscale (Casella and Fowler, 2005). It challenges the search for the universal category of 'kin-based co-residential domestic group' and embraces the richness of the diversity of the social context of domestic action that has been forefronted in social anthropology for many years (Moore, 1988). It lifts the household domain out of its previous position of 'assumed general knowledge' and as marginal to the 'great events' of history. It provides a richly-based, multiscalar theoretical framework to consider the role of the labor of players in prehistory: women, men and children (Tringham, 1991).

The theoretical basis of feminist anthropology and social practice theory obviously creates some serious epistemological challenges to the scientific logical positivist methodology that characterizes mainstream processual (new) archaeology. It is as difficult to identify 'gender' in archaeological architecture as it is to find 'households' and 'families.' Responses to this challenge have been articulated in many publications (Hodder, 1999; Wylie, 1992). They are based in a celebration of the ambiguity of archaeological data, a critical awareness of the scientific process of inference, and a richly researched

utilization of sources for interpretation – ethnography, history, art and literature. Above all in the post-processual epistemological framework, archaeology is identified as an interpretive discipline rather than a hypothetico-deductive search for true (pre)history (Baugher-Perlin and Spencer-Wood, 2010). Thus in order to think about the prehistoric construction and practice of gender ideologies and dominance relations within or between households, a researcher may interpret the archaeological data and their meaning in many ways. It is not required to identify gender or 'domestic unit' in the archaeological record.

The database for an archaeology of gendered places remains especially but not exclusively in the record of the built environment. Along with the nature of household archaeology itself, however, the excavation and interpretation of archaeological architecture has changed. According to post-processual concepts, the built environment can be thought of as both a passive container that has a use-life and reflects social action and as an 'active' arena or medium for and symbolic expression of social actions. Thus social actions, practices, negotiations, and dominance ideologies of whoever passes through a building are constrained and channeled by the materiality of that building. (Tringham, 1994). In practice this has led to the necessity of retrieving a highly detailed microstratigraphic record of the traces of human activity, in which the sequence of every depositional event is recorded and interpreted. It is time-consuming, expensive, but immensely rewarding (Hodder, 1999; Tringham, 1994).

Along similar lines, more recent household archaeology has embraced the ambiguities recognized by practice theory anthropologists about kinship categories, including 'family' and 'household.' In their view, it is the meaning and cultural value ascribed to a relationship that are significant rather than some set of biological ties (Gillespie, 2000). The enactment of kinship often involves the negotiation of identity and the identification of relationships through particular places on the landscape – buildings and sets of material culture (Joyce, 2000).

At the beginning of the twenty-first century, 'what households do' is still a focus of household archaeology, but the 'doing' is far more complex than physical action. Moreover, a 'co-resident domestic group' is no longer a faceless economic category, but comprises the complex life-histories of many people as well as buildings and places. Finally, household analysis is no longer a step along the ultimate goal of understanding social evolutionary change. It plays an essential role in the creation of a multiscalar history that considers such questions as how – in practice – was a sense of place created; how was social memory about this group maintained; what were the myths about garbage; what would the walls of a house say if only they could speak (Tringham, 2000).

Household Economics

Abstract

Household economics analyzes all decisions made by households at both the microeconomic and macroeconomic level. One influential tradition based on the New Home Economics emphasizes the role of household production and takes a microeconomic perspective. It includes unitary models conceiving of the household as a unified decision-making unit and models recognizing that individual members of multiperson households keep their own preferences and constraints. Applications include all decisions possibly made by households, such as labor supply, consumption, savings, demand for health, time uses other than paid work, household financial arrangements, migration, marriage and divorce, other sexual behavior, fertility, demand for education, intergenerational transfers, and home-leaving by adult children. Household economists are interested in the effects of a wide range of government policies on household decision making. Many of these applications of household economics have been pursued independently, but recently there is a tendency for more integration and cross-fertilization between the various models that can be classified under the umbrella of 'household economics.'

Household economics analyzes all decisions made by households, including those regarding consumption, savings, labor supply, leisure, home production, health, education, fertility, marriage, divorce, environmental protection, emotional well-being, and participation in institutions.

There are many kinds of households. Most – but not all – households are families living together, and therefore household economics overlaps with economics of the family. It also overlaps with demographic economics.

History

Even though Malthus and some other classical economists wrote on fertility and other household decisions, at the end of the nineteenth century the marginalist revolution moved the focus of economics to market transactions and pushed part of household economics into a black box. The parts of household economics that continued to be studied by mainstream economists include consumption and labor supply, two areas closely tied to the monetary economy. During this period, some agricultural and home economists studied household production (e.g., Reid, 1934). The New Home Economics (NHE), a movement toward the reintegration of the household into economic analysis, was initiated by Nobel laureate Gary Becker and Jacob Mincer at Columbia University in the 1960s (Grossbard-Shechtman, 2001; Grossbard, 2011).

Some Key Modeling Assumptions

Five elements of theoretical models of the household are considered here: number of household members, subject matter of the decision, type of decision making, consideration of household production, and number of time periods considered.

The most common household models assume one-person households and analyze decisions regarding consumption, savings, and labor supply. Regarding type of decision making, if multiperson households act as if they were one unit the models are called 'unitary,' a term introduced by Browning et al. (1994). Some unitary models assume that the household has one altruistic head, which leads everyone in the household to act in the household's best interest, even a 'Rotten Kid' (Becker, 1981). A problem with unitary models is what Apps and Rees (2009) call the anonymity implication: unitary models assume that it does not matter who within the household earned a particular income. This implication has been refuted by many (a partial summary is provided by Haddad et al., 1997).

Alternative models have assumed that individual members of multiperson households keep their own preferences and constraints (Donni and Chiappori, 2011). These alternatives include consensual models, models of independent individual decision making, and bargaining models. Consensual models follow Samuelson (1956) in assuming that households have a social welfare function reflecting a household consensus. Independent individual models – such as Becker's (1973) competitive marriage models, Keeley's (1977) marital search model, and Grossbard-Shechtman's (1984) model of marriage and labor markets – assume that marriage markets are in equilibrium and that individuals with separate preferences and constraints agree on exchanges based on equilibrium prices established in markets. Bargaining models assume that household members play games of a cooperative (e.g., McElroy and Horney, 1981; Chiappori, 1988) or a noncooperative nature (e.g., Konrad and Lommerud, 1995). All three types of nonunitary model analyze how outcomes vary according to factors such as age, sex ratios in marriage markets, and divorce laws on intrahousehold distribution of goods and individual access to leisure (and thus labor supply). Becker (1973) coined such factors market factors, McElroy (1990) called them extrahousehold environmental parameters (EEP), and Browning et al. (1994) 'distribution factors.'

Household production plays a key role in many household decision-making models, starting with the original NHE models of consumption (Mincer, 1963; Becker, 1965; Lancaster, 1966) and labor supply (Mincer, 1962). Models also differ in terms of the number of periods that they consider.

 http://dx.doi.org/10.1016/B978-0-08-097086-8.94008-X

Microeconomists tend to develop one-period models, an exception being Ghez and Becker's (1975) early dynamic model of consumption and labor supply. Macroeconomists – who often analyze time series – are more likely to consider changes over time. A recent survey of macrolevel time use analyses can be found in Aguiar et al. (2012). Furthermore, related economic analyses of home production in farming households have continued within the discipline of agricultural economics (e.g., Taylor and Adelman, 2003).

A Wide Range of Applications

Household economics continues to cover the study of labor supply, consumption, and savings, as was the case before the arrival of the NHE. However, in the 50 years since the birth of the NHE, many more areas of application have sprung up.

Grossman (1972), also part of the NHE, pioneered the use of household production models in analyses of household demand for health (see also Anderson and Grossman, 2009). This has become a large field, including the study of obesity (e.g., Fertig et al., 2009) and other harmful behaviors. Among the early applications of household production models to the study of time uses other than paid work are those by Biddle and Hamermesh (1990) and the analyses reviewed by Juster and Stafford (1991). Time allocation models examine a variety of time uses, from sleep (Biddle and Hamermesh, 1990) to social interactions (Saffer and Lamiraud, 2012) and household activities conserving the environment (Matsumoto, 2013).

Household economics includes the study of household financial arrangements (e.g., Woolley, 2003; Negrusa and Oreffice, 2011) and migration. Also included are the study of marriage and divorce, applications that originated with Becker (1973), and of other sexual behavior, including timing of first intercourse (e g. Cannonier, 2012) and marital fidelity (Fair, 1978; Smith, 2012; Bishai and Grossbard, 2010). Unmarried cohabitation among heterosexual couples (Grossbard-Shechtman, 1982) and the division of chores work inside the household are also part of the subject matter (Becker, 1981; Gimenez-Nadal and Sevilla, 2012). The formation of same-sex couples is a recent and growing application of household economics (e.g., Jepsen and Jepsen, 2002; Badgett et al., 2008; Grossbard and Jepsen, 2008; Negrusa and Oreffice, 2011).

Children are a major focus of household economics. Microeconomic analyses of fertility were pioneered by Leibenstein (1957) and Becker (1960) and have generally assumed that couples made fertility decisions as one unit. Browning (1992) summarized a large portion of the economic literature dealing with children and published prior to 1980. More recent studies examining women's decision to have a child either alone or as a couple include that by Ekert-Jaffe and Grossbard (2008). Analyses of children based on a collective model also introduce individual differences between the spouses (e.g., Cherchye et al., 2012). Parents invest in their children in different ways, including caring for them (Folbre and Yoon, 2007), paying for their education, choosing between sending them to school and to work (Kis-Katos, 2012), and giving them monetary transfers (Becker, 1981). Economists study such investments in the context of a wide range of children outcomes (e.g., Currie, 2011; Conway and Li, 2012; and Cunha et al., 2010). Gifts of time and money from children to older parents have also been analyzed by household economists (e.g., Becker, 1981; Pezzin et al., 2009) and so have unmarried adult children's decisions to live away from their parents (e.g., Le Blanc and Wolff, 2006; Del Boca and Chiuri, 2010).

Policy, Laws, and Technology

Household economics is interested in the effects of a wide range of government policies on household decision making. This encompasses inter alia the effects of taxes on labor supply (e.g., Beninger et al., 2006), of drug policies on drug consumption (e.g., Becker et al., 2006), and of paid parental leaves on fertility and labor supply (e.g., Datta Gupta et al., 2008).

Household economics also analyzes how laws affect outcomes of household decision making. This includes studies of the effects of divorce laws on divorce (e.g., Becker, 1981; Wolfers, 2006) and labor force participation (e.g., Peters, 1986; Chiappori et al., 2002), marriage laws on economic growth (e.g., Schoellman and Tertilt, 2006) and fertility (e.g., Guttierez and Suarez Beccera, 2012), property laws on maintenance of physical capital (e.g., Ellickson, 2008), and bride price refundability on sexual fidelity (Bishai and Grossbard, 2010).

A relatively new area of research deals with the effects of technological changes in household production on economic growth (e.g., Greenwood et al., 2005) and fertility (Bailey and Collins, 2011). How changes in contraceptive technology have affected fertility and wages (Bailey et al., 2012) as well as labor supply (Goldin and Katz, 2002; Oreffice, 2007) is also a relatively new direction for research on household economics. With the increased availability of merged household and firm data it is hoped that economists will also produce analyses of how firms' policies toward their workers affect various household outcomes such as labor supply and fertility (Grossbard-Shechtman, 2003).

Toward More Integration

Since the start of the NHE in the 1960s, household economics has experienced big leaps forward. However, these leaps have been uneven, with some applications and methodologies leaping more than others. For a long time microhousehold economics dominated, but in recent years the growth in macrohousehold economics is noticeable. In part, it has been propelled by the increased availability of time use data both at the national and international levels. However, the expansion of household economics into the study of outcomes not previously considered part of economics characterizes the microapplications of household economics more than its macrolevel applications, and the more empirically oriented researchers more than the scholars specialized in theory.

More integration and cross-fertilization between the various branches of household economics would be desirable. Given that similar theoretical and empirical models can often be applied to many different kinds of outcomes being researched, there is much to gain from models developed separately for the

study of a restricted set of household outcomes being exported to researchers dealing with different household outcomes. This holds for both theoretical and empirical models and micro- and macroeconomic models of household decisions.

Journals such as the *Review of Economics of the Household* and the *Journal of Population Economics,* as well as edited books such as *Household Economic Behaviors* (Molina, 2011), contribute to such cross-fertilization by publishing a variety of models dealing with household economics.

Households in Anthropology

Abstract

Anthropologists use the term household loosely to refer to a residential unit, whose members cooperate in some activities of production, consumption, or child rearing. They differentiate the household from the family by defining the former as a residential unit and the latter as a kinship unit. Close scrutiny of this distinction reveals key assumptions that have shaped the way anthropologists and other social scientists have conceptualized and studied not only households, but also families, domestic groups, and kinship.

Problems in Defining the Household

The grounds for analytically separating families and households lie in the broader claim that kinship and locality are two distinct principles of organization (Keesing, 1958). This claim, in turn, derives from the discipline's focus in the nineteenth and early twentieth centuries on the principles organizing social groups and relations in nonstate societies. Kinship, which was assumed to be universally defined on the basis of genealogical linkages rooted in biological reproduction, was considered the most important among these principles. As a key mode of recruiting members to (and limiting membership in) politically important groups such as lineages and clans, kinship (genealogical propinquity) was distinguished from locality (spatial propinquity), which defined residential units such as hamlets and villages. As anthropologists expanded their range of ethnographic research to include peasant communities, they drew on the distinction between kinship and locality to differentiate family from household. The family as a corporate kin group was distinguished from the household as a collection of kin and sometimes nonkin who share a common residence. The corporate character of the peasant family was viewed as rooted in the jural rights to property, usually land, which its members held in common. Family members supposedly retained these rights regardless of whether they were members of the same household. Hence, family and household, it was argued, are both 'logically distinct' and 'empirically different' (Bender, 1967: 493).

Actual usage of the term household in the anthropological literature, however, calls into question both the logical distinction and the empirical difference between families and households. For one, residential units composed of individuals who are not genealogically linked, such as orphanages, college dormitories, men's houses (in societies where gender segregation among adults is practiced), convents, and army barracks, usually are not considered households. At the same time, however, families whose members move between residential units that are located on different continents are referred to as 'transnational households' (Basch et al., 1994; Jones and de la Torre, 2011). As a general practice, anthropologists attach the term household only to groups of people that share both a common living space and activities that are identified as domestic. Domestic activities include those activities related to food production and consumption or to reproduction, including childbearing and child rearing. As these are the very same activities that are considered the functional basis of the 'family,' in practice, households are identified using both 'kinship' and 'residence' criteria. Thus, the claim for the logical distinction and empirical difference between family and household is not affirmed by scholarly practice.

Because 'domestic' activities are sometimes carried out by groups of people who do not reside together, some anthropologists (Bender, 1967) have suggested that it would do better to employ alternate terms in our ethnographic descriptions. Among the alternatives that have proposed are 'coresidential group,' 'budget unit,' and 'domestic group.' Less important than the terms employed, however, is the need for ethnographers to describe precisely the composition, organization, activities, and functions of these units. In addition, the cultural meanings people attach to them must be explicated (Yanagisako, 1984). In the absence of this knowledge, anthropologists are likely to project their own cultural meanings and expectations on those units.

The difficulties of identifying households are illustrated by innumerable cases (see Segalen, 1984), which demonstrate that neither the boundaries nor the functions of household are easily discerned. Questions have been raised as to how to treat residential groups that move through a seasonal cycle of dispersal and concentration, how to handle the movement of people between dwelling units, whether to define as a single household the huts or houses that share a common yard or those that share a common stove, and whether to include servants, apprentice, boarders, lodgers, and nonkin in the household. More recently, studies of transnational migration (Rouse, 1991; Basch et al., 1994; Parreñas, 2005; Boehm, 2012) have raised the question as to whether residential units located on different continents constitute a single household. As the speed and ease of long-distance communication have been revolutionized by new media, including instant messaging, e-mail, and video calling, some scholars (Madianou and Miller, 2011) have claimed that the nature of family relationships is changing. Although the emerging scholarship on digital media and migration has focused on families rather than households – sometimes slipping between these terms – it remains to be seen whether new forms of communication will lead to the reconceptualization of what constitutes a household. Since studies of gay and lesbian kinship (Weston, 1991) effectively challenged the assumption that heterosexual marriage and parenthood are the universal,

 http://dx.doi.org/10.1016/B978-0-08-097086-8.12088-4

natural core of families, studies of gay and lesbian households have increased.

Problems in the Classification of Households Types

Much of the literature on households has been concerned with explaining variation among households that are distributed over time and space. In describing this variation, most scholars have focused on the character of the genealogical links between the members of the household as its defining feature. Terms, such as 'stem-family household,' 'nuclear family household,' and 'patrilateral extended household' are based on the configuration of genealogically defined kin types included in the household – in other words, its household composition. In addition, the most genealogically 'close' members of the household are assumed to form its structural core. If a household contains two adult brothers, their wives, and children, it is labeled a fraternal-joint household. The assumption here is that the relationship between the brothers constitutes the structural core that shapes the relations of all the members of the household. Accordingly, studies of household change over time track changes in the genealogical composition of the household.

The classification of households on the basis of their genealogical composition rests on the shaky assumption that people who are similarly linked genealogically will have the same or greatly similar social relations. In other words, it is assumed that the labeling of a household as a 'stem-family household' captures its organizational structure and function. But, a stem-family household found at one time and place does not necessarily share the same organizational dynamics as a stem-family household at another time and place. A household, or any social unit, is much more than the sum of its genealogical links. It is the negotiated outcome of the culturally meaningful actions and relations among its members. The actions and relations of households' members with identical genealogically defined links can differ radically. Even households with the same genealogical composition in the same community may have significantly different structures of authority and divisions of labor, and they may engage in a range of different activities (Yanagisako, 1984).

What Explains Variation among Households?

A key question that has fueled comparative studies of households by anthropologists, sociologists, historians, demographers, and other social scientists is what explains variations among them. Two related questions have been asked of variations observed in household composition. First, why do a significant proportion of the households in a society differ from what people report to be the ideal type of household? Second, irrespective of these ideals, what explains the distribution of household types within and between societies? Three types of variables have been offered to answer both these questions: demographic variables, economic variables, and social stratification variables.

Demographic variables affect the size and composition of households, thus acting as constraints on the attainment of the culturally ideal household type. Age at marriage, life expectancy, and fertility shape the composition of households at any given time in a population. The economy of the household is also shaped by demographic processes. Among peasant for whom the household is the unit of production, changes in the demographic structure of the household as it moves through the developmental cycle entail changes in the ratio of consumers to workers (Chayanov, 1966).

Fortes's (1958) model of the developmental cycle of domestic groups draws on these demographic processes to explain the varieties of domestic groups found in a society. Fortes hypothesized that the variety of household types found in a community or society at any point in time are merely different phases in the developmental cycle of a 'single general form.' As all households pass through different stages of the developmental cycle at different times, a census taken at a particular point in time will catch only a few in the ideal, complete phase. Hence, an ideal household type, such as the patrilineal stem-family household of Japan (which includes a married couple, their adult son and his wife and children) is better regarded as "a transitory state in the development of the household, rather than as a form" (Hammel, 1975: 142).

Fortes's model has been useful in helping us understand the impact of events, such as birth, marriage, and death on the composition of households. It cannot account for all the observed variation in households, however, because other cultural and social forces (see below) are also involved. Fortes himself later (1978: 18) conceded that a model of a uniform developmental cycle could not explain why the actual histories of different families entail different developmental sequences. The model may also blind us to historical shifts wherein more recently formed households embark on a different trajectory than older ones. In addition, while demographic factors undoubtedly shape households, it is a mistake to treat them as exogenous, biological constraints on the composition and economy of households. To do so confuses social replacement with biological reproduction and overlooks the strategies people actively employ to control household size and composition, including practices of marriage, fosterage, adoption, timing and spacing of births, and timing of household division. The collection of longitudinal data on households, whether by drawing on historical sources or through retrospective oral histories, is necessary to understanding both continuity and change. Cohort analysis is an effective tool for helping ascertain similarities and differences in the household histories of members of successive cohorts, defined on the basis of year of birth, marriage, or other historically significant events experienced by the members of a community.

Economic variables are also adduced to explain cross-societal variation in household composition and organization. In some cases a mix of 'economic' and 'ecological' factors, including labor needs of production, defensive needs, care of children, taxation, and conscription practices of the state, are identified as the functional basis for the prevalence of certain household types. In others, the labor requirements of a particular productive activity are singled out as the primary determinant of household type. In their cross-societal analysis of 60 randomly selected societies, Pasternak et al. (1976) conclude that labor requirements are the most powerful determinant of the formation of extended family households.

They hypothesize that in societies where work outside the home makes it difficult for a mother to tend to children and other domestic tasks or where the outside activities of the father make it difficult for him to perform his subsistence work, extended family households will prevail. Although they are able to demonstrate a correlation between activity requirements and presence of extended family households, they lack diachronic data to support the hypothesized causal relation between their independent variable (activity requirements) and their dependent variable (presence of extended family households). Consequently, they must resort to arguing that it is more plausible that activity requirements cause extended family households rather than vice versa. It seems as plausible, however, that household composition and productive activities do not lie in a simple, unidirectional causal relation but instead shape each other.

Attempts like that of Pasternak et al. to identify the determinants of household composition and structure through statistical analysis of cross-societal comparisons have declined significantly over the past 40 years as the inherent problems and limitations of such studies have been increasingly recognized. Among these problems is that of discerning whether appropriate units have been selected for comparison. As all societies contain different frequencies of a range of household types, it is misleading to classify entire societies into those with 'extended family households' versus those with 'independent family households.' A better understanding of the relation between household composition and 'economic' factors and processes may be gained by investigating the ways in which diverse types of households in a society articulate with one another rather than by reducing the entire society to a single household type.

Labor requirements are frequently used to explain the frequency with which a particular household type appears in a society or section of society. Netting (1974) cites several ecological studies as demonstrating that household composition among horticulturalists and agriculturalists varies with the type and amount of labor required for effective crop production. His own study attributes the differences between the large, extended families of shifting cultivators, and the nuclear family households of intensive agriculturalists in the same Nigerian plateau environment to different labor requirements (Netting, 1965).

Both cross-societal and intrasocietal studies that seek the determinants of household variation in productive labor requirements assume that once having identified the primary productive activity of the household, researchers can ascertain its labor requirements and proceed to show how the household efficiently meets them. In doing so, however, they tend to overlook the fact that it is not simply technological requirements that necessitate a household type, but the entire manner in which production is socially organized. In other words, a productive activity can be accomplished by a variety of household types depending on how that production is socially organized, including the division of labor by sex and age, the use of hired labor, cooperation between households in productive tasks, and the exchange of labor between households. In assuming that the household is a self-contained labor unit, researchers fail to sufficiently investigate the existence of other forms of labor organization. The social units engaged in production may not be the same at different phases of the productive cycle. For example, different social units may work together in the planting, weeding, and harvesting of crops. To attribute household composition to labor requirements begs the question, because it assumes the prior existence of an entire social organization of production, including age and gender divisions of labor. To overcome this narrow focus on the technical requirements of production, the interplay of a wider range of cultural, political, and economic forces shaping productive relations within and between households must be considered.

Social stratification: differential access to resources, in particular differences in ownership and control of the means of production, also shape household variation in both peasant communities and urban, industrial populations. A past tendency to neglect social stratification in studies of households and other domestic groups can be attributed to the past assumption that the communities studied by ethnographers were basically homogeneous. When anthropologists studied peasant communities, for example, the stark contrast with the landowners – who were generally not studied – led them to overlook significant differences among the peasants. Consequently, there has been a tendency to overlook stratification as a significant factor in the analysis of household variation among peasants. Yet, peasant communities are rarely homogenous; instead they are usually internally differentiated. Differences in wealth among peasants are also often obscured by kinship ideals and commitments that connect the landed to the landless and the land-rich to the land-poor. Significant wealth differences may exist, however, between the smaller coresidential units of a single kin-based compound or between brothers, who head the main and branch households of a family. In other words, ideologies of family and kinship may obscure stratification among kin.

Changes in Households over Time

Anthropological studies of household and family change over time have generally focused on the effects of industrialization, urbanization, and the increasing integration of communities into capitalist market relations. Some of these challenge or argue for the refinement of the dominant social theory that family, household, and kinship decline in importance as a society 'modernizes' and becomes increasingly urbanized and industrialized. They demonstrate that, in some cases, urbanization and industrialization have strengthened the extended family rather than weakened it and that new functions are assumed by extended families and extended family households. For example, urban migration may contribute to the maintenance of extended family households. While these studies provide an important correction to the theory of modernization and kinship decline, they are marred by the inconsistent use of ambiguous terms, including 'extended family household.' The argument over whether extended families have declined with urban-industrialization is in part the result of differences in the way in which researchers define and conceptualize household type. Quite often it is assumed that people who live in extended family households pursue common strategies and cooperative actions under the direction

of a central authority – the head of the household. This not only gives undue weight to centralized authority as the defining feature of the extended family, but it also overlooks the heterogeneity in the goals and strategies of the members of a household.

Critical Approaches to Household

The adaptationist, utilitarian approach to households that prevailed in much of the anthropological literature up until the 1980s has been challenged by theoretical shifts in the discipline that have had an important impact on the discipline in general. Among these perhaps the most significant has been the emergence of feminist theories of gender.

In the 1970s, one of the first questions feminist anthropologists raised in rethinking anthropological analysis of women's status and roles was whether ethnographers had overlooked women's goals, strategies, and forms of action, especially in the 'domestic sphere.' M. Wolf's (160) study of Taiwanese joint family households, for example, revealed that family and household division was brought about as much by women's attempts to advance their own goals and those of their 'uterine family' as it was by conflicts among brothers. Collier (1974) argued that this process occurs commonly in societies where men gain power by holding together large bodies of coresident kin, but where women (especially younger women) gain power by breaking up such units. By attending to the informal power women often wield in societies where men are granted formal authority, feminist anthropologists alerted us to the tensions and conflicts and, therefore, the complex processes shaping households and other domestic groups. Likewise, investigations of women's relations with kin and others outside their household demonstrated that it is not just men who link mother–child units to larger institutional structures. The involvement of women in informal exchange networks between families and households had been overlooked by androcentric studies that had equated male relations with the 'public sphere.' Once studies showed that the female and male members of households – as well as the young and the old, those born in the household and those who had married into it – often do not share the same goals and strategies, it was no longer possible to retain the naive concept of a unified 'household strategy.' Finally, by calling into question the presumed universality and immutability of gender identities and the gender division of labor, feminist anthropologists denaturalized gender systems and called for the study of its historical and cultural production. They revealed the gender assumptions embedded in concepts of the 'public' and 'private' spheres (Reiter, 1975), in definitions of the 'domestic sphere' and 'domestic groups,' including family and household (Yanagisako, 1979) and in theories of kinship in general (Yanagisako and Collier, 1987).

Rethinking Households

Functionalist analyses of 'household adaptation' reified the household, treating it as a social actor endowed with human consciousness and motives. Households were described as having goals, fashioning strategies, and adapting to the changing pressures of a modernizing society. Such language demonstrates the ease with which an analytic construct can be reified into a social actor. The imputation of consciousness and will to households is rooted in the assumption that those who live together share a collective motive and will – in other words, a unified household strategy. It obscures the complex social processes through which people negotiate the relations that produce households, despite different and sometimes conflicting goals, strategies, and ideas about what it means to 'live together.'

Neither the composition nor the dynamic structure of households can be understood without a thorough understanding of the cultural meanings and sentiments that shape the social actions and relations of the people who live in them. This does not mean that households cannot be compared across societies, but rather that any comparative study of households must explicate the culturally specific and heterogeneous meanings and motives shaping people's residential preferences and relations. Such an expanded strategy of research and analysis will enable anthropologists to move beyond crude comparisons of distributions of genealogically defined household types within and across societies to understanding households as the negotiated outcomes of culturally meaningful action.

Abstract

We live in an urban age. Most people now live in cities and cities are mostly housing. This article emphasizes the centrality of housing in everyday life and as a focal point of social and political conflict. It highlights the connections between housing and the life course, health, education, and social status. It describes the key terms that social scientists have employed to explore housing and cities and the different theoretical perspectives that have been used to explain the distribution of urban housing.

Introduction

In the middle of the nineteenth century, Britain became the first country in the world where more people lived in cities than in rural areas. Some 150 years later, around 2010, the rest of the world had reached that point. Whichever country we are living in, we are now likely to be city dwellers. The major cities are still places of power and government. Some are still places of manufacturing. But more than ever they are places of residence. A process of proletarianization and rural–urban migration that began in England in the eighteenth century continues today on an even greater scale. From the vantage point of Western Europe or North America, industrialization and mass migrations from the countryside to rapidly expanding cities are seen as historical phenomena. However, from an African, Latin American, or Asian perspective these processes are very current and are generating many of the same kinds of urban problems that were evident in previous centuries in Northern Europe and North America. People flock to the cities in search of a better life, pulled by the prospects of better wages and pushed by social disadvantage and the land dispossessions of encroaching urbanization and corporate landgrabs (Araghi, 2009). When they get to the city, however, they often struggle to find decent housing amidst a straining infrastructure that cannot cope with the accelerating population influx. The result can be overcrowding, declining sanitary conditions, and disease.

In Engels' nineteenth century Manchester or Sims' nineteenth century London, housing conditions could be appalling. Keating's (1976) selection for the social explorers of Victorian cities offers this description:

> The room when we entered it was in a condition beyond description. The lady was washing the baby, and she made that an excuse for the dirt of everything else. Two ragged boys were sitting on the filthy floor, a dirty little girl was in a corner pulling a dirty kitten's tail, and the smoke from the untidiest grate I ever saw in my life was making the half-washed baby sneeze its little head nearly off. The family, all told, that slept in this room was seven. There was a bed and there was a sofa-so I concluded the floor must have been the resting-place of some of them. (p. 76)

Closely comparable descriptions could be found of housing conditions in contemporary cities but probably in other parts of the world. The geography of urbanization and industrialization may have changed but housing inequalities remain stark. Indeed, from a global perspective, it could be argued that housing problems in cities are getting worse rather than better. Slum housing is endemic and homelessness, overt and hidden, accounts for millions of urban residents (Tipple and Speak, 2009).

The condition and location of housing connects to all the key aspects of everyday life in the city, including schooling, employment opportunities, social status, and personal wealth. It is precisely this pivotal position of urban housing to the shaping of life chances that has made it such a politically charged and contentious field. Conflicts in cities are, and have so often been, around housing issues of residential segregation, the redevelopment of residential neighborhoods, evictions and displacements, and housing costs. The Glasgow Rent Strike in 1915 is the best-known historical example, notable because it was organized mainly by working class women and during wartime. Manuel Castells' *The City and the Grassroots* (1983) highlights the importance of housing issues in mobilizing urban protest or 'social' movements in a wide range of social and cultural contexts. Such bottom-up demands for better housing, or resistance to redevelopment, have strong class dimensions but may also be rooted in shared identities of gender, ethnicity, or sexual orientation.

Naming the Parts

At the simplest level, housing in cities is usually described and classified in terms of 'tenure' or whether people own or rent. Renters either rent from private landlords, public landlords, or from a housing association or housing society. These latter kinds of landlords may have charitable or quasicharitable status and may have religious or trade union foundations. In the past, large employers provided rental accommodation but this has generally declined in importance in most countries.

Urban home ownership, as distinct from more traditional rural-based, semifeudal ownership, can be divided between mortgaged and outright ownership. If a person is an urban home owner, the person will probably have borrowed money from a bank, building society, or some other kind of financial institution. The person only actually owns the property when that loan is paid off, typically close to or at retirement. In some societies, the family also remains an important source of financial assistance for housing, particularly for young people seeking to buy their first home.

Much of the housing literature focuses on movement or nonmovement between different types of tenures as a key element of residential differentiation in cities. The classic progression in more affluent societies is for children to leave the parental home and rent privately for a while before buying their first home. For lower income households, purchase may be too expensive and social renting may be a short-term or long-term housing destination.

Tenure patterns vary across societies as do definitions of tenures. Historically, private landlords were dominant providers in expanding cities but declined in importance as forms of home ownership and public or social landlordism became established. The private landlord class often comprised a myriad of small-scale property owners, perhaps with only one or two properties to rent. High-speed urbanization generates housing demands that necessitate a more coordinated, institutional response requiring large, private financial institutions and/or state intervention. Thus, private landlordism tended to survive best in countries where it had a strong institutional foundation, as in the former West Germany.

It is often believed that there is a close relationship between growing affluence and levels of individual home ownership – a linear model with rising incomes and rising individual property ownership growing in tandem. However, some of the richest countries in the world, such as Switzerland, Japan, or Germany, have relatively low levels of home ownership. To understand and explain the cases of Switzerland and Germany or any other country's housing patterns, and how these patterns have evolved in specific cities, thus requires an understanding of distinct social and political histories and of institutional structures and relationships. Harloe's analysis of the development of different forms of social housing after the Second World War is an excellent example of this approach. He shows the particular and contingent relationships and circumstances involved in the development of social or public housing in different societies. Kurz and Blossfeld (2004) offer an equally nuanced analysis of home ownership and social structures.

By way of summary, two dimensions of urban housing provision should be highlighted. The first relates closely to the preceding discussion of tenures but is also aimed at complicating these categories. Housing analysts have often conceptualized urban housing provision in terms of 'commodification' and 'decommodification.' In other words, what proportion of a city's housing is provided via market mechanisms or allocated on some other basis such as bureaucratic assessment of need? Second, how important are informal processes? How far are property rights formally recognized and formally regulated? Here, the author refers most typically to unauthorized or illegal, self-build types of housing associated most closely with the cities of the developing world.

Millions of people find their own housing solutions in the absence of formal and/or affordable forms of provision. It has been estimated that over a third of the urban labor force in developing countries are housed in the informal sector. When we think therefore of housing in cities, we need to think beyond the regulated and formal forms of provision of the Western city and consider the critical role of informal self-provision. Moreover, without the initiative and resilience shown by poor migrants to cities, many aspects of the so-called formal sector would be unsustainable. For example, it is often the poor and marginal and those in the informal housing and labor market that do the critical recycling work of cities – foraging among the urban detritus as a means of survival.

Thus, when we consider housing and cities, the conventional starting point is usually tenure – who owns and who rents? However, such categories contain such variation of circumstances and conditions within and between societies that they lack explanatory power. It is more appropriate to think about housing and cities in terms of formal/informal or commodified/decommodified and to see such categories as continuous rather than polar opposites. These concepts can then be applied to different stages of the housing process in cities – through its production, distribution, and exchange. These different stages involve a range of institutions and actors, including government, quasi-government, private and voluntary sectors, households, and families. Ball and Harloe (1992) referred to such configurations as "structures of housing provision" – "combinations of social agents involved in housing provision that relate to each other in empirically observable ways" (p. 3).

Connections

David Donnison, an early and influential housing specialist, neatly captured the centrality of housing to so many aspects of the everyday life of urban populations. In his introduction to *The Government of Housing* (1967) he observed that "House and home stand at the center of people's lives, providing a shelter for sleep and for half their waking activities, a shield against the elements and the world-which yet admits both in a selective and controlled fashion and a storage place and showcase for most of their possessions. To study housing is to explore a cross section of a whole society and its affairs" (p. 9). The dwelling is thus a key nodal point, symbolically and practically. Where you live and what you live in are important signifiers of your social status. You are judged consciously and unconsciously, purposively and inadvertently, by your address. High-status addresses cost money. The rich live in big houses. Wander around any city and see social status imprinted on the residential structure. It is one of the most visible expressions of social division. Moreover, as information technology has become increasingly sophisticated in its capture and deployment of household data, addresses have become much more than mere signifiers of social status. Zip codes or postcodes now convey risk and danger, safety and desirability, and investment and disinvestment. They show whether certain neighborhoods contain 'people like us' or 'the others,' whether they are places to avoid or places to embrace. And residential reputation may hinder or enhance employment opportunities.

Various urban analysts have observed that the contemporary city is a city of walls and enclaves (e.g., Marcuse, 1995). These walls may be virtual and metaphorical. People living in the same neighborhood or even the same street may occupy different worlds. They may share the same space but have little in common. In recent decades, these barriers and distinctions have taken on an increasingly physical reality. There are real walls that distinguish and separate different kinds of housing. Gated residential communities have

multiplied in rich and poor countries. They may be demographic communities (for the retired, for the young family) or defensive communities protected by electronic gates, security cameras, and private guards. This is not a new phenomenon. Historically, many cities had private and usually prestigious residential areas, often with imposing gates and bylaws specifying what was and was not allowed within the perimeter. But gating is now pervasive and is without doubt a defining feature of housing patterns in the contemporary city (Webster et al., 2002). It is also a notable feature of social status and social security, particularly in the affluent residential enclaves of the expanding cities of Asia, Latin America, and Africa.

Demography is also a major factor to consider in relation to urban housing. The stage in the family life course affects not only the choice of dwelling type, dwelling size, and the affordable price but also the critical connections. The classic life cycle model progresses from leaving the parental home to getting married, having children, the departure of children, retirement, and eventual mortality. The first stage after leaving the parental home represents the need for a new dwelling unit and the last stage releases an empty unit for reuse. As individuals progress across the life cycle, households typically grow in size (full nester household with children) and then shrink when children leave (empty nester). Of course, this has always been an approximate and idealized version of real life. Housing histories are messier and some argue that the modernized version is less predictable than was the case for previous generations. People stay single for longer, relationships break down, and adult children return home for a while. There is more divorce and more remarriage, women have children later in life, there is greater longevity, and so on.

When a family breaks up, two housing units are required rather than one. One or both partners may lack the resources to buy or rent in the market and need social housing of some kind. Changing social norms and behavior generate new types of demands for housing. City housing built for one generation has to accommodate the very different demands of the next. This results in formal and informal adaptations. Large houses become flats. Rooms are subdivided. Once fashionable areas become the reception areas for poorer migrants to the city. In many European cities, much of the housing is well over a century old. For example, a fifth of the dwellings in the United Kingdom, France, or Italy were built before 1918. During building booms and even in cities where there are few institutional or other barriers to redevelopment, it would typically take half a century to replace the building stock. Even if that were achieved, building forms could never keep pace with changing social norms.

However we conceive of the family life course in relation to urban housing, different groups will have different needs and preoccupations. This will affect locational and other residential preferences. Younger single people and childless couples spend less time at home and will probably want to be more immersed in the urban milieu than families with young children. Young families are likely to seek bigger gardens on the suburban or rural fringes; as children reach their teens, the pressure on parents will be to return to a more urban environment. One of the most critical issues for families with children concerns schooling. Here the connection between residential location and school choice can be direct. Geographical catchment areas can determine the majority of allocated places to schools. Schools acquire good and bad reputations. In cities where market processes dominate, strong reputations translate into higher house prices. Real estate agents further reinforce this process and neighborhoods with the most desirable schools become expensive places to buy. Even if there is a substantial social housing sector, school catchment areas are likely to affect the pattern of allocations. Those able to wait, the least desperate, can hang on until a dwelling in the right location becomes available. This interface between housing and education has become a major battleground in many cities as families vie for position in increasingly competitive education markets. In knowledge-based societies where the returns for high-quality education seem to be increasing (as do the penalties for low levels of education) and where in many societies one child is the norm, this competition has become more intense. For aspirant parents with resources, the choice may be between paying for expensive private education or moving to a more expensive neighborhood. For poorer households, the problem is that the best schools may become colonized by those able to pay higher property prices. This process can thus reinforce existing patterns of social and spatial disadvantage.

A full appreciation of the dynamics of neighborhood change is beyond the scope of this article. The key point to emphasize is that housing cannot be separated from its neighborhood context or from broader issues of residential design, planning, and architecture. Here, there are links to current debates about the future shape of cities and to environmental concerns about urban sprawl and the need for higher density living. Residential planning can also reflect and reinforce class and ethnic segregation.

More fundamental challenges to the design of dwellings and neighborhoods have often come from feminist writers arguing that cities are essentially designed by men for men. The suburban ideal in particular has been critiqued as predicated on the male breadwinner model and dependent on the unpaid domestic work of women. "Despite very real differences in the structure and support for suburban living, women everywhere were taken for granted as its main custodians and beneficiaries and separated, appropriately enough it was assumed, from male-dominated economic and political activity in the city" (Strong-Boag et al., 1999; 171). The world may have moved on somewhat, at least in some societies, but even today few would challenge Dolores Hayden's assertion in 1984 that "no country has yet created an urban fabric and an urban culture to support men and women on equal terms as citizens and workers" (p. 232).

Understanding the Distribution of Housing in Cities

Social scientists have approached the question of who gets what housing, and why, from different theoretical perspectives. Housing is both physical form and social construction. What is built, when, by whom, and for whom are ultimately social and political processes involving the exercise of power, which is unequally distributed. Although most people can exercise some choice about where they live, such choice is exercised within highly variable constraints.

Addressing these issues conceptually is most easily conceived of in terms of approaches that focus on individual behavior, those emphasizing institutional actors and those adopting a more structural perspective. These approaches overlap and are not necessarily mutually exclusive.

By far the most significant influence on studies of housing and cities has been the work of the Chicago School of the 1920s and 1930s. Chicago, at that time, was one of the most rapidly expanding cities in the world and Park, Burgess, McKenzie, and associates used the city as a laboratory to explore the dramatic social and economic transformations that were taking place. The key features of the ecological approach, and its shortcomings, are well-trodden ground and those seeking detailed elaboration should consult the suggestions for further reading. But essentially, the city was conceived of as a built environment in which individuals and groups competed for survival. As in the natural world, this competition involved processes of invasion, displacement, and succession. The evolving structure of cities could be understood therefore as a biological model, mediated but not primarily determined by, cultural factors. The research agenda and conceptual schema were understandably a reflection of the forces shaping Chicago at that time. Here was a city expanding rapidly through in migration with the central business district (CBD) encroaching on the residential areas in the city center. This process pushed the population outwards into the suburbs leaving behind 'zones of transition' – areas of residential decay and falling property values awaiting commercial and industrial redevelopment. It was these cheap areas of dilapidated housing in the inner city that provided accommodation for poorer migrants to the city.

While the work of the Chicago School has been critiqued for being strong on description of the changing residential patterns but weaker on explanation, it represents the first systematic, social science research on urban residential processes. It was the foundation stone for sociological analysis of contemporary urban society – indeed, for sociology as a discipline. Moreover, although there have since been considerable theoretical advances in understanding the processes that sort and sift residential areas, its basic approach to analyzing urban social structures has influenced generations of urban geographers and sociologists. It is also often forgotten that the Chicago research encompassed ethnographic work on processes of adaptation and assimilation into this new way of urban life, and on social groups on the margins of urban society. It was thus the forerunner to various studies of residential communities, both mainstream and marginal, which followed.

In research on housing and cities, mainstream economics kept itself somewhat distant from the other social science disciplines. This can be partly attributed to the greater importance attached to disciplinary purity among economists compared to say sociology or geography – the disciplines that have tended to dominate urban studies as a subdiscipline. However, neoclassical economics has made an important and distinctive contribution in this field. Individual competition has always been the hallmark of neoclassical economic models. In the context of household residential preferences and demands, one thus has utility maximizing subjects trading housing costs against transport costs. Stated simply, housing costs decrease, and transport costs increase, as we move further from the CBD. These models became increasingly sophisticated and included additional trade-offs and locational influences including leisure, densities, neighborhood characteristics, environmental quality, and ethnicity. Economists were particularly influential in the development of ideas of 'filtering' as a way of understanding the operation of housing policies, housing markets, and housing submarkets. One application of filtering theory was in relation to vacancy chains – the chain of moves set in motion when a dwelling is vacated. For example, building a new dwelling at the top end of a housing market may generate a long series of moves ultimately releasing a cheap dwelling at the bottom end of the market. Unsurprisingly, such models have been controversial in housing policy debates.

Neoclassical economists' concerns with the aggregate effects of individual residential locational decisions can be linked to another strand of research that emerged in the 1960s. This drew particularly on psychology and the sociology of the family and the household to explore perception and decision making. Residential mobility within cities came under closer scrutiny. Why did households move? How did individuals, households, and groups respond to changes in the external environment? This generated increasingly complex models of the process of residential location and of the interaction between internal (e.g., family size) and external (e.g., changing neighborhood characteristics) drivers of mobility decisions. One of the best known studies of residential mobility actually preceded much of this literature and had a strong social policy orientation. Rossi's *Why Families Move?*, originally published in 1955, was concerned with a perceived dysfunctional pathology of American society. Postwar United States was characterized by excessive mobility that potentially threatened social cohesion and ideas of community. The research reassuringly found that residential mobility was, however, primarily driven by family growth factors rather than by some innate, pervasive, and unrelenting desire to move among contemporary Americans.

In the 1960s, the field remained dominated by studies that gave preeminence to the role and experience of the individual in housing systems and that tended to neglect or downplay the wider socioeconomic/political context in which housing choices were made. The latter part of this decade, however, saw significant changes in approaches to housing and cities. As with the Chicago research, issues of immigration and segregation were also the main driving forces for the classic study undertaken in Birmingham, UK, by John Rex and Robert Moore. Published in 1967, *Race, Community and Conflict* set out to develop a sociology of race relations through an exploration of urban segregation in area of Birmingham, which had become a key reception point for new black immigrants to the city. In doing so, they explicitly drew on the ecological ideas of the Chicago School combined with a Weberian conception of classes as status groups – in this case, housing classes. Rex and Moore described a process of city growth involving migration from the central areas to the suburbs. Two forces were at work here – the expansion of the CBD and a common pursuit of a middle class, suburban lifestyle. The professional class moved to the detached houses in the inner suburbs; the lower middle class to semidetached suburbia, and a skilled working class to public housing suburbia. This process of migration involved the progressive abandonment of the nineteenth century housing. The less prestigious Victorian housing was bought

up by landlords and sublet as lodging houses to new migrants creating a twilight area of short life properties, physical decay, overcrowding, and a poorer immigrant class. In this competition for housing resources, there was a status hierarchy. At the top were the outright owners of whole houses followed by owners of mortgaged dwellings. At the bottom were tenants of rooms in lodging houses. The achievement of suburban home ownership was a 'scarce resource' in which there were winners and losers. The pattern of housing distribution could thus be the basis for potential conflict between different groups.

With regard to race relations, the concern was the perceived cleavages between a white middle class in suburban home ownership, a white working class in public rental housing, and the black immigrant population. Because of income barriers and eligibility rules for public rental housing, new immigrants were effectively excluded from the two main forms of urban housing provision. Previously, the literature on urban housing had focused on residential choice and mobility, on atomized individuals competing in the market. The significance of Rex and Moore's study was that it emphasized conflict and constraint, was explicitly rooted in sociological theory, and linked spatial form and social process.

Inevitably, their analysis was subject to considerable critique. For example, the assumption that all groups were competing for the same scarce resource, suburban home ownership, was questioned by some as was the conception of housing classes as the basis for social conflict. Could the struggle over housing really be analyzed as a class struggle over the distribution of life chances in the city – a domain of class conflict distinct from the world of work? Was it not the case that the distribution of housing reflected, rather than caused, social stratification? Both Weberians and Marxists had more to say on this issue.

From a Weberian perspective, the British sociologist Ray Pahl, focused on the role of urban gatekeepers as a key element of the wider context in which individual choices were exercised (Pahl, 1967). Housing choices were not made in a vacuum but within conditions created by the various institutions and actors that controlled the production and allocation of housing and other urban resources. Pahl was still concerned with spatial patterns and saw residential location as an inherent source of inequality and conflict since every space is unique. The issue was how a particular spatial distribution occurred. For Pahl, the key to understanding the spatial distribution of housing lay in the way power was exercised, and decisions made, by urban managers. This *urban managerialist* perspective spawned a whole series of research studies on banks, building societies, real estate agents, local governments, and landowners. The decisions of mortgage lenders or those who allocated public housing were argued to be crucial to explaining sociospatial distributional patterns in the residential city. Particular controversial issues related to the redlining (or whitepainting) of neighborhoods by lending institutions, thereby starving them of mainstream lending and thus, it was argued, reinforcing a downward spiral of decay.

Again, race and ethnicity were central to these discussions. In these institutional studies, the social and spatial consequences of lending or allocation decisions were often attributed to the attitudes and prejudices of particular institutional actors. However, the unjust distribution of housing resources was more likely to be the product of more complicated intra-institutional dynamics. Sometimes decisions taken at different levels of an organization, and for unconnected reasons, combined to produce discriminatory outcomes.

It should be noted that urban managerialism, as a distinct approach, had more academic and policy traction in Europe, and notably the United Kingdom, than in North America. Some commentators have suggested that this is because of the more interventionist character of housing provision in Europe compared to the more market-driven housing markets in the United States and Canada. Housing resource allocators, especially with regard to social housing, were more visible in places like Britain.

A more fundamental break with previous conceptions of the production, distribution, and consumption of urban housing came from within the Marxist paradigm. A fundamental conceptual problem with the managerialist/institutionalist perspective (which Pahl himself recognized) was that 'the managers' of housing systems could not be blamed for creating scarcity – they merely had to make decisions on how to allocate scarce housing resources. The Marxist literature seemed to offer an answer. Urban housing was produced, consumed, and distributed according to the logic of contemporary capitalism. Cities, and thus housing provision, were shaped according to the needs of capital accumulation. Housing tenures (ownership, private renting, and public renting) were economic devices to speed up the rotation of capital in cities. Cities were conceived of as essentially 'transaction maximizing systems' with residential real estate as a key sector for capital investment and realization. Conflicts over housing were class struggles in a system in which inequalities were endemic. The early Marxist contributions powerfully shifted the focus of analysis from individuals and institutions to social and economic structures. In doing so, they were often criticized for being overly economistic. People often seemed to have disappeared from view under the weighty analyses of the economic forces shaping housing provision in the capitalist city. The problems of methodological individualism in work on urban housing had been theoretically addressed but in doing so, much of the richness and detail – the understanding of everyday life in residential areas – seemed to have been lost. Housing might be capitalist but there were different forms of capitalism and different capitalist cities with distinct cultural, economic, political, and policy histories. It was thus recognized that there was a need to work back from the high level of abstraction offered by Marxist writers on housing toward studies that allowed more room for temporal and spatial contexts.

Concluding Observations

Reflecting on housing and cities at the end of the first decade of the twenty-first century, four aspects stand out. First, under postmodern influences, ideas of diversity and difference in housing have seen renewed interest in detailed ethnographies and community-type studies of neighborhoods. In other words, there has been recognition of the need for more empirical research on the experience of contemporary city life – a return to some of the original concerns of the Chicago School. Second, and conversely, urban housing is more than ever

conceived of economically rather than socially. Residential real estate has been deeply implicated in various financial crises and economists have become more interested in the impact of housing markets on wider economies (*Critical Review*, 2009). Third, as indicated earlier, in China the pace of urbanization and of new residential construction is unprecedented. Social science research on housing and cities has been predominantly focused on Western developed societies and cities. New conceptual tools are now required to capture the changed social and cultural geography of housing and urban development. Fourth, the last three decades or so has been the era of neoliberal policy dominance. Urban housing has generally been in the forefront of market-driven policy developments whether in the United Kingdom, China, or Russia. The longer term consequences of these major political and policy shifts in relation to housing provision are only now emerging and are likely to become a focal point of future research on housing and cities.

Abstract

This article reviews the economics of housing. The organization is conventional. The first three sections treat the microeconomics of housing. The first section reviews the demand for housing, the second the supply of housing, and the third section how demand, supply, and the allocation mechanism (principally markets) interact to determine the allocation of housing. The fourth section treats two subjects that build on housing microeconomics, real estate economics (housing from an investment perspective) and real estate macroeconomics (principally housing market cycles and fluctuations). The final section reviews housing policy.

Housing Economics

Housing has a set of characteristics that together make it different from all other commodities, which are as follows:

1. Necessity: Housing satisfies a basic human need, shelter.
2. Importance: Most households spend more on housing than on any other class of commodity.
3. Spatial fixity: Most housing units are rooted to a particular location. Living in a particular housing unit, a household, therefore, consumes not only the characteristics of the housing unit per se, but also the characteristics of its location – its neighbors and neighborhood, its accessibility to other locations, its taxes and public services, and its locational amenities and disamenities.
4. Durability: Housing is the most durable of major commodities. If built soundly and maintained well, a housing unit will last virtually indefinitely.
5. Heterogeneity and complexity: To describe a housing unit reasonably accurately requires enumerating very many characteristics (complexity). Also, housing units exhibit considerable heterogeneity in characteristics, and households exhibit considerable heterogeneity in tastes.
6. Housing as an asset: Because housing is durable and the expenditure share on housing high, the housing stock constitutes a substantial proportion of a nation's wealth and of most households' portfolios. The demand for housing, therefore, combines consumption and asset motives.
7. Housing and the macroeconomy: Since housing is durable, modest fluctuations in housing demand translate into large fluctuations in housing investment. Due to the importance and volatility of housing investment and the magnitude of the wealth effects generated by movements in housing values, the performance of the housing market can have a major impact on the macroeconomy.

The interactions of these characteristics cause the economics of housing to be significantly different from the economics of other commodities. Section Housing Supply will examine the supply of housing and Section Housing Demand the demand. Section Housing Allocation and Markets will discuss how supply and demand interact to determine equilibrium in the housing market. Section Real Estate Economics will look at the housing market from the perspective of real estate economics. Section Housing Policy will consider the role of government with respect to housing. The focus throughout will be on housing economic theory, in contrast to empirical work.

Housing Supply

Before discussing how housing is supplied, a quantifiable definition of 'housing' is needed. The appropriate definition depends on context. In some contexts, highly aggregated definitions that ignore housing heterogeneity – the number of units or total floor area – are most useful. In other contexts, each housing unit is usefully viewed as a bundle of many characteristics. In yet other contexts, intermediate levels of aggregation are most helpful. The definition employed strongly influences the way the market is conceptualized and housing supply and demand described.

Most housing economics is conducted at a high level of aggregation. A nation's monetary authority is interested in the value of the nation's housing stock and the level of housing investment, not in where housing units are located within cities or how many units have two bedrooms. Similarly, the government's housing ministry is principally concerned with housing affordability, crowding, sanitary facilities, and structural soundness, and not in how many units have fireplaces.

At the highest level of aggregation, a housing unit is described simply by the flow of housing services it provides, which can be measured by its rent. Holding its characteristics fixed, an increase in the unit's rent corresponds to a rise in the price of housing services. A housing supply curve may then be defined relating the units of housing services supplied to the price of housing services. Because housing is durable, the elasticity of the housing services supply curve depends on the time horizon. Within, say, a month, the housing supply curve is almost vertical; little can be done beyond maintenance to increase the quantity of housing services supplied. As the time horizon increases, the housing services supply curve becomes increasingly elastic; within 6 months, a rise in the price of housing services will induce some rehabilitation; within a year, some new housing will be constructed; and so on.

In many situations, the analyst is concerned with the interaction between particular housing submarkets. For example, the government might be interested in the effects of

a subsidy on owner-occupied housing. To analyze this policy, the housing market would be divided into owner-occupied and rental submarkets. The two submarkets would interact on both the supply (the subsidy would encourage the conversion of housing from rental to owner occupancy) and demand (the subsidy-induced fall in the consumer price of owner-occupied housing services would cause a decrease in rental housing demand) sides. Other divisions of the housing market into submarkets are appropriate in other contexts. If the government is concerned with the living standards of the poor, the housing market is usefully divided into quality submarkets; if it is concerned with downtown revitalization, a division into downtown and suburban submarkets is suitable; and so on.

The discussion thus far has treated the supply for housing services, which is a flow. Lurking in the background is the supply of housing stock. The two are related through the user cost of capital (which is the ratio of the annualized cost of employing a unit of capital to its supply price, and equals the interest rate plus the rate of depreciation plus the maintenance cost rate less the rate of capital gains) and the opportunity cost of land, with appropriate adjustment for the various taxes applied to housing. Housing economists are sometimes careless in failing to distinguish two 'prices' of housing – rent, the price per unit of housing services per unit time, and value, the asset price of a unit of housing stock.

In the short run, rent adjusts to clear the market for housing services. This translates, via the user cost of capital and the opportunity cost of land, into the equilibrium asset price or market value of housing. If the market value of housing exceeds the market value of land plus construction cost, new construction is triggered, which increases the supply of housing stock and of housing services, causing rent to fall. This process continues until a long-run equilibrium is attained where the market-clearing rent equals construction cost times the user cost of capital plus the opportunity cost of land.

The above conceptualization of the housing market is especially well suited for aggregate analysis. The remainder of the section reviews several alternative conceptualizations, each of which has its particular domain of application.

The focus of the Mills–Muth model (see Mills (1972) and Muth (1969), and Brueckner (1986) for an integrative treatment) is on urban spatial structure – how housing density (the ratio of floor to land area), housing rent, and land rent vary with location. Ignore the spatial fixity and durability of structures, so that static analysis can be applied. A landowner adds capital to his land until marginal factor cost equals marginal revenue product. Under competition, land rent equals the corresponding producer's surplus. This analysis relates land rent and housing density to housing rent at a particular location. At the level of the market, housing rents adjust so that in equilibrium at each location the quantity of housing supplied equals the quantity demanded, with more attractive and accessible locations commanding higher rents. Then from the relationship between housing rent and housing density, the equilibrium urban spatial structure is obtained.

The Mills–Muth model ignores the durability of structures. A related class of models, reviewed in Brueckner (2000), examines the spatial structure of a growing city, accounting for durability. A developer who owns vacant land then faces the decision of when to build as well as at what density. The relationship between predevelopment land value and post-development housing value and density can be straightforwardly derived. Normally vacant land is developed from the center outwards. Subsequently, there are successive waves of redevelopment. Each wave entails construction at higher density with the time between waves depending on the city's growth rate. This process is evident in some cities but in others has been curtailed by redevelopment restrictions.

The Mills–Muth model and dynamic durable housing models treat location, housing density, and unit size. Housing units also differ in quality. If two housing units of the same size at the same location command different rents, the higher rent unit is presumably of higher quality. Since the poor typically live in low-quality housing, quality differentiation is particularly important to consider when evaluating policies aimed at improving low-income housing. Models of housing quality differentiation examine the filtering process (Grigsby, 1963). An urban location goes through a life cycle. Housing is of high quality when constructed but depreciates with age, and as it does so is occupied by successively poorer households. Eventually, rehabilitation/renovation or redevelopment of the site at higher density becomes profitable, and the cycle repeats. Since the typical neighborhood was initially developed in a short time span, the filtering process gives rise to neighborhood cycles too. Filtering models suggest that it is efficient for the poor to live in hand-me-down housing, which provides an argument against public housing – housing constructed and operated by the government specifically for occupancy by poor households.

More recent filtering models (Sweeney, 1974; Arnott et al., 1983; Rothenberg et al., 1991) view the housing market as a hierarchy or continuum of quality-differentiated submarkets. At any instant, the housing market is described by the housing stock at the various qualities. Rent as a function of quality adjusts to clear the market. Construction occurs at those qualities where housing value equals or exceeds construction costs plus the value of land. Maintenance is carried to the point where the last dollar spent increases housing value by one dollar, and a housing unit's value is the present discounted value of rent less maintenance expenditures. These models can be enriched to treat housing differentiation by unit size, location, and density (Anas and Arnott, 1991).

Filtering models provide a strong conceptual basis for policy analysis and are intuitively appealing, accommodating all the standard housing conversion processes – construction, maintenance, rehabilitation, upward and downward conversion (combining and subdividing housing units), abandonment, and demolition and reconstruction. Despite their popularity among academic housing economists, filtering models have not yet been widely adopted by the housing policy community.

Working with detailed descriptions of housing units is normally distracting, but in measurement is essential. The minister of housing may be uninterested in whether the poor have fireplaces (as long as they receive heat), but is interested in whether the average quality of low-income housing has increased. This requires obtaining a quality index, an aggregate of many housing characteristics – including fireplaces. Investors, housing policy analysts, and macroeconomists are all concerned with the time trend of housing prices, which

requires developing price indices. And for tax assessment purposes, housing values need to be estimated accurately, which necessitates detailed description. Hedonic analysis utilizes such detailed description. The market values (or rents) of housing units are regressed against a long list of their characteristics (including public services, neighborhood and neighbor characteristics, accessibility measures, and environmental variables). The regression coefficients are interpreted as implicit market prices for characteristics (Rosen, 1974). Hedonic analysis has proved very useful not only in housing valuation and housing price and quality index construction, but also in inferring the market's valuation of various neighborhood characteristics, such as parks, trees, and improved air quality. But the implicit conceptualization it employs – separate markets for each of the hundreds of housing characteristics – is unwieldy for most housing policy analysis.

Industry studies focus on market organization – industry concentration and the form of strategic interaction between firms. The conventional wisdom that the housing market is competitive or monopolistically competitive, while inadequately researched, appears sound.

Housing Demand

The previous section indicated that how housing supply is described depends on how housing is conceptualized. The same is true of housing demand. Most housing demand studies employ the housing services conceptualization. Accordingly, there is a very large empirical literature estimating the income and price elasticities of demand for housing services. Excellent reviews are provided in Goodman (1996) and Olsen (1986). Muth, whose classic *Cities and Housing* (1969) provides the foundation of modern housing economic analysis, has argued that since the housing expenditure share has shown remarkable stability over time and location – about 25% of after-tax income – the long-run price and income elasticities of housing must be close to unity. Most empirical studies, however, estimate significantly lower price and income elasticities. How can the results of these empirical studies be reconciled with Muth's observation?

The literature has concentrated on four classes of explanations as follows:

1. With high moving costs (including psychic costs), a household does not instantaneously change its housing when its income or the price of housing changes; rather, housing decisions are long term. This explains why experiments investigating how households alter their housing consumption under temporary rent subsidies have found a generally price-inelastic response. Relatedly, the demand for housing should depend more on permanent than on transitory income.
2. That many moves are triggered by demographic change (e.g., marriage, births, retirement, and divorce) makes it more difficult to identify the economic determinants of housing choice.
3. Tenure choice with borrowing constraints. The typical household starts its life cycle by renting, often underconsuming housing to save up for the down payment on an owner-occupied housing unit. Having saved up enough, it moves into a starter home or condominium, aiming to trade up when it can afford to. The timing of these moves depends on the realization of the household's uncertain income prospects and demographic changes, and on the evolution of housing prices, interest rates, and down payment requirements.
4. The asset or portfolio demand for housing. When deciding how expensive a home to buy, a household considers how much housing it would like to include in its wealth portfolio. A household's demand for owner-occupied housing achieves a balance between its consumption and portfolio demands. Households adjust the discrepancy between these demands through tenure choice, customization, and furnishing (Henderson and Ioannides, 1983). A household whose asset demand exceeds its consumption demand may purchase a large home but spend little on decoration, or may purchase additional housing units and rent them out. A household whose asset demand falls short of its consumption demand may choose either to own a cheaper house and decorate it nicely or to rent.

Estimating price and income elasticities accounting for all these complications, as well as the tax treatment of housing, is indeed a daunting task. Despite these difficulties, considerable progress has been made in the empirical analysis of housing demand, reflecting advances in data collection, computing power, applied econometrics, and housing economic theory, and in the use of controlled experimentation. Regrettably, however, little work has been done on estimating filtering models (Rothenberg et al., 1991 is a notable exception), which has impeded their use in policy analysis.

Housing Allocation and Markets

Throughout history, most consumer goods have been allocated through markets. The twentieth century witnessed a sharp rise in the size and scope of government. The communist countries adopted central planning, which entailed government construction, operation, and direct allocation of housing. Elsewhere too, government intervention in the housing sector increased. For a quarter century the pendulum has been swinging in the opposite direction, but by historical standards government intervention in the housing sector remains high. Even in the United States, with the most free market of Western economies, much low-income housing continues to be allocated outside the market, and the allocation of market housing to be deliberately influenced by a myriad of government policies.

Why have governments everywhere doubted the ability of markets to allocate housing? Textbooks in microeconomic theory give a standard list of (classic) market failures or inefficiencies – public goods, natural monopoly, and technological externalities. None is important in the context of housing. The primary motive for extensive government intervention vis-à-vis housing has rather been to improve equity. Some believe that the income distribution generated by the free market is just but most do not. How then is equity to be achieved within a generally market-oriented economy? There are two broad approaches. One is income redistribution, general

egalitarianism; the other is effective redistribution through the taxation/subsidization or nonmarket allocation of specific commodities, specific egalitarianism. Most economists favor general egalitarianism because it respects consumer sovereignty. But most governments evidently favor specific egalitarianism. They – and the person on the street – feel that the consumption of some goods (basic housing, clothing, food, education, and medical care) is more meritorious than others (alcohol, cigarettes, drugs, and luxuries). Many governments have favored the nonmarket allocation of housing for the poor over subsidization, because it permits more refined targeting and may be administratively simpler. There has been remarkably little modern economic analysis of nonmarket housing allocation (Anas and Cho, 1988, is a notable exception). The rest of the section will, therefore, consider how the market allocates housing.

The central contribution is Alonso (1964). He asked: How does the market determine the pattern of household location within a city? Suppose that there are two household groups, rich and poor, that each household derives utility from only other goods and housing floor area, and that locations differ only in accessibility. In equilibrium, all rich households achieve the same utility level (otherwise migration would occur from low-utility to high-utility locations). Associated with this utility level is the equilibrium housing bid-rent curve for the rich, which indicates the housing rent (per unit floor area) payable by the rich at different locations consistent with this utility level. The equilibrium bid-rent curve for the poor is derived in an analogous manner.

Two basic principles apply: (1) A housing unit goes to whomever bids the most for it and (2) rent equals the bid rent of whomever bids the most for it. The top panel of **Figure 1** plots the equilibrium bid-rent curves for the two groups as a function of accessibility, a. Applying the two principles implies that housing between accessibility levels a′ and a″ goes to the rich and that between a″ and a‴ to the poor, and that housing rent as a function of accessibility is given by the 'upper envelope' of the equilibrium bid-rent curves. The lower panel of the figure shows the stock of housing available at different

Figure 1 Equilibrium bid-rent curves.

accessibility levels. The equilibrium utility levels are determined by the conditions that, for each group, the quantity of housing demanded equals the quantity of housing supplied. The slope of a group's housing bid-rent curve is the premium that group is willing to pay for improved accessibility. As drawn, the poor outbid the rich at more accessible locations because they are willing to pay a higher premium per unit floor area for improved accessibility. This result has been used in explaining the post-World War II suburbanization of wealthier US households.

The accessibility-rent tradeoff is central in determining the pattern of household location within a metropolitan area. The above analysis can be extended to treat other factors, such as the relative value different groups attach to amenities, disamenities, public services, environmental quality, and neighborhood quality and composition. Each group has an equilibrium bid-rent surface over all locations within the metropolitan area, and lives where it outbids all other groups. Groups may differ not only in income but also in demographic status, race, job location, etc. Extending the analysis to account for taste heterogeneity within groups yields the probabilities that a particular location is occupied by a household in a particular group. The same competitive allocation mechanism operates with respect to other housing attributes.

The asset value of a housing unit is the discounted present value of expected future rents minus expected costs, adjusted for uncertainty. The volume of construction depends on profitability, as measured by asset price minus supply price; similarly, the volume of rehabilitation depends on the gain in asset price through rehabilitation minus the cost; and maintenance expenditure depends on how steeply housing value rises with quality.

The above discussion indicates how a perfectly competitive housing market works. In actual housing markets, housing units and households exhibit multidimensional heterogeneity. To find a unit that suits its tastes, a household undertakes costly search over vacant units. The friction of search confers market power on landlords, who are consequently price-setters rather than price-takers. With entry and exit close to free, actual housing markets are, therefore, more accurately described as monopolistically competitive, with excess capacity taking the form of vacant units. Furthermore, housing markets are matching markets, with market tightness (the ratio of searching households to vacant units) playing an important role in the market adjustment process. Down payment requirements on mortgages and credit restrictions on developers also significantly affect the market's operation. These are typically treated as exogenous but should be derived as a feature of equilibrium.

Whether the gain in accuracy from treating the housing market as monopolistically rather than perfectly competitive justifies the increased analytical complexity, is an empirical issue and depends on context. Normally little is sacrificed in using perfectly competitive models to analyze the positive effects of specific housing policies. But imperfectly competitive models should be used to provide microfoundations for housing macroeconomics since nonprice adjustment is important, and to evaluate welfare changes from housing policies.

In the frictionless world of perfect competition, and without taxes, a household would be indifferent between renting and

owning. That tenure choice is in fact important indicates that it should be considered from the perspective of imperfect competition. Though often treated in the context of housing demand, tenure choice is an aspect of market equilibrium since it concerns the contractual form through which housing services are exchanged. Renting and single-family owner occupancy are the most common contractual forms; others include condominium ownership (under which common areas are jointly owned) and cooperative ownership (under which a resident is essentially a shareholder in the building). With ownership comes extended property rights, including claim to the property's capital gains, stronger legal protection from search, more privacy, and the ability to customize, but also increased risks and responsibilities.

Real Estate Economics

How does residential real estate economics differ from traditional housing economics? Both are concerned with the housing sector, but real estate economics regards it from an investment perspective, housing economics from a policy perspective, especially public policy with respect to housing the poor. The state of real estate economics 20 years ago was excellently surveyed in DiPasquale and Wheaton (1996). In the intervening 20 years, reflecting the shift from public to private provision of housing, much of the best research on housing economics has been done under the rubric of real estate economics.

One important development has been the extension of real estate investment theory to treat uncertainty satisfactorily. Because real estate investment decisions are made under uncertainty, which gradually resolves itself, and are largely irreversible, they are usefully viewed as the exercise of real options (Titman, 1985; Capozza and Li, 1994), to which the theories of options valuation and irreversible investment can be applied.

Traditionally, housing macroeconomics was concerned with the relationship between housing macroeconomic variables (stocks, starts, completions, house values and rents, the mortgage rate, and down payment constraints) and how they are affected by the state of the macroeconomy and monetary policy, as well as with the internal dynamics of real estate cycles (Stein, 1995 is an important early paper). The housing sector in turn was viewed as affecting the broader macroeconomy through investment and employment in the construction industry. Over the last quarter century, two major changes occurred in financial markets that have increased the interdependence between the real estate sector and the rest of the economy. The first was the liberalization of mortgage markets, which allowed financial institutions considerably more flexibility than before in their design of mortgage instruments. The second was the creation of secondary mortgage markets (mortgage-backed securities) that allowed banks to diversify their mortgage risk. After a mortgage crisis in the US in 2008 triggered the Great Recession, study of the real and financial links between the real estate sector, especially the housing sector, and the rest of the macroeconomy, has intensified.

Drawing on the theory of asymmetric information, the microeconomic side of this literature has focused on the optimal design and regulation of contracts between banks and borrowers, developers and contractors, landlords and tenants, and homesellers, homebuyers, and real estate agents. Private contracting should be regulated so that private contracts allocate risk efficiently and provide appropriate incentives. Of special interest has been the appropriate regulation of mortgages and mortgage-backed securities, and of their markets.

Macroeconomists have come to recognize that the real estate sector affects the rest of economy in ways other than just through investment and employment in the construction industry. In the US, between 1983 and 2008 real home prices almost doubled, resulting in very large positive wealth effects that stimulated consumption and investment throughout the economy; the subsequent fall in housing prices during the Great Recession had a corresponding dampening effect. Excessively liberal mortgage financing and weak regulation of secondary mortgage markets led to widespread mortgage default, a banking crisis and a more general financial crisis, as well as undermining consumer confidence. Macroeconomists (e.g., Iacoviello, 2005) have responded by adding housing and housing finance modules (though taking the form of the mortgage borrowing constraint as given) to their models, which are linked to the rest of the economy, through not only the employment market but also the banking sector. To satisfactorily link the microeconomic and macroeconomic literature will require relating the equilibrium set of mortgage-finance related contracts to the state of the macroeconomy and of financial regulation.

Housing Policy

Housing policy debates tend to pit economists against planners and other social scientists. The divisions between the two groups are social philosophical. Since economists value individual freedom to choose, they hesitate more than planners to impose their vision of the good life on others. Also, economists generally emphasize efficiency and believe it is best achieved via markets, with government enforcing property rights and intervening minimally to mitigate market failure, while planners tend to be suspicious of markets, objecting to the inequities and apparent disorder they generate. For all these reasons, planners almost invariably favor more government intervention than do economists.

The planner's view dominated housing policy in western Europe from the 1920s through to the 1980s, especially in the Scandinavian countries where housing markets were largely supplanted by government allocation. The objective of decent and affordable housing for all was largely achieved, but at the cost of considerable inefficiency. During the last decade, these countries have been dismantling the Byzantine housing allocative and regulatory structures that had evolved, and moving to increasingly free housing markets. Thus, the economist's view is currently in the ascendancy.

Economists' belief in the efficiency of markets is at least well reasoned. Two central results in microeconomic theory are the First Theorem of Welfare Economics, which states that under perfect competition a market equilibrium is efficient, and the Second Theorem, which states that (under convexity conditions) any efficient allocation can be achieved as a competitive

equilibrium with appropriate lump-sum redistribution. If, therefore, an economy were to satisfy the Theorems' conditions, efficiency and equity could be simultaneously achieved if the government only enforces property rights and redistributes income appropriately, leaving everything else for markets to do, and almost all government intervention in the housing sector would be harmful. Whether real world economies come close to satisfying the Theorems' conditions is clearly crucial in determining the appropriate role of government in housing provision, and therefore needs to be considered carefully.

Through the 1980s, most neoclassical economists believed that, since buyers and sellers are many and entry and exit free, housing markets are almost perfectly competitive. Nowadays, most housing economists would disagree. Housing markets have many characteristics that violate the assumptions of perfect competition: housing is a heterogeneous good; transactions costs are important; asymmetric information is endemic; and insurance and futures markets in housing are highly incomplete. As well, because the government cannot observe an individual's 'need' but must instead infer it from a signal (e.g., income) that the government can manipulate, all redistributive policies are distortionary. Equity is then most efficiently achieved through a portfolio of policies, including perhaps housing assistance for the poor. Since the optimal portfolio is sensitive to details of the economic environment, housing economists now tend to base their policy advice as much on the results of controlled experiments and empirical studies as on a priori reasoning. While consideration of market imperfections expands the scope of potentially ameliorative government intervention, the political economy literature warns that government, too, is highly imperfect.

Government withdrawal from the housing sector has been especially pronounced in direct housing provision. The current view is that low-income housing projects were a mistake. They led to the alienation and ghettoization of the poor, and were excessively costly (since it is efficient for the poor to live in filtered-down housing). Low-income housing policy in the United States today encourages household mixing by race, ethnicity, and income, through subsidizing the nonpoor to live in the projects and the poor to move into middle-income neighborhoods. Other countries are experimenting with selling project units for owner occupancy.

A classic debate in housing economic policy is whether intervention is more effective on the demand or supply side of the market. Generally speaking, housing demand policies can achieve better targeting, but may drive up rents in the short run until the lagged supply response kicks in. Unlike most other safety-net programs, households eligible for housing subsidy programs are typically not entitled to benefits, which are instead rationed.

Virtually all housing policies apply to either rental or owner-occupied housing but not to both. Most policy makers encourage homeownership, believing it to foster social behavior, civic responsibility, and commitment to neighborhood. The empirical evidence is, however, weak since controlling for the effect that responsible and well-functioning households are more likely to choose homeownership is difficult. Furthermore, homeownership is especially risky for low-income households. Homeownership is encouraged through subsidized and guaranteed mortgages, mortgage interest deductibility under the income tax, tax inducements for first-time homeownership, and subsidies for home improvements.

There are several other elements common to the housing policy debate in most countries.

1. Rent control (reviewed in Arnott, 1995): Economists have been virtually unanimous in their opposition to traditional (now termed 'first-generation') rent controls, which impose ceilings on rents below market-clearing levels. Almost all jurisdictions that have had first-generation rent controls have either dismantled them or replaced them with second-generation programs that stress tenant security rather than rent reduction.
2. Tax policy: Most countries use tax policies to achieve housing policy goals.
3. Eviction rights versus security of tenure: The nature of the landlord–tenant relationship bears the seeds of conflict. Policy concerning protection against eviction for nonpayment of rent entails a classic tradeoff between risk sharing and incentives. Predictably, relative to the United States, European jurisdictions favor the tenant.
4. Zoning, building codes, and density and height restrictions: These significantly affect the spatial pattern of rents and hence household location by income-demographic group. In many cities, height and redevelopment restrictions have forced up downtown property values, driving many poor households previously resident there to surrounding locations. Also, affluent North American suburbs have used minimum lot size zoning and other regulations to exclude the poor.
5. Antidiscrimination: Housing audits have been used in the United States to identify discrimination. A pair of individuals, one of whom belongs to a potentially discriminated-against group, are paid to pose as prospective tenants or prospective homebuyers, and are given the same resume; differences in their treatment are then attributed to discrimination. Also, recent empirical research has attempted to identify discrimination by banks in mortgage lending.
6. Homelessness: In most Western countries, homelessness is now a very visible housing problem. While many causes are sociological – the weakened bonds of family and community, higher mobility, deinstitutionalization of the mentally ill, and increased drug use – economic causes are important too (O'Flaherty, 1996). The withdrawal of governments from the housing sector has caused low-quality housing rents in many cities to rise so much that homelessness is a rational response for some very low-income individuals and households.

Due to rapid population growth and urbanization, by 2050 most of the world's largest cities will be in developing countries. Unlike European and North American cities, their cities tend to have dual housing markets, a formal and an informal housing market. Informal housing ranges from squatter housing to housing in violation of zoning and building regulations, and has dubious legal status. Furthermore, many of these cities are in countries with large informal economies, resulting in household income being difficult to measure. Informality raises a special set of issues with respect to housing policy (Arnott, 2009).

Human Behavioral Ecology

Abstract

Behavioral ecology is an explicitly Darwinian approach to the study of behavior. It emphasizes the adaptive value of behavior patterns of individuals as they attempt to solve social and environmental problems that affect their chances of survival and reproduction. The goal of human behavioral ecology is to explain behavioral diversity as a consequence of environmentally contingent responses made by individuals. While some studies show differential reproductive outcomes, most studies rely on proxy measures of fitness. As such, it is the application of a series of behavioral models from evolutionary biology such as optimal foraging theory, parental investment, life history theory, kin selection, reciprocal altruism, and mating strategies. Much of the research to date has focused on behavioral strategies of producing food, resource transfers, marriage, investing in offspring, and managing social interactions between offspring, mates, kin, and unrelated individuals. A large fraction of this work has been accomplished by anthropologists working among traditional peoples.

Aside from behavioral ecology, evolutionary approaches to the study of human behavior fall under a variety of names such as sociobiology, biocultural or biosocial science, human ethology, socioecology, evolutionary anthropology, evolutionary ecology, gene-culture coevolution (or dual inheritance theory), and evolutionary psychology (Cronk, 1991: p. 25). While some of these names are synonyms, others represent different emphases described below. Human behavioral ecology attempts to explain behavioral diversity as a consequence of environmentally contingent responses made by individuals in their attempts to maximize their inclusive fitness. Critical to this goal is the specification of environmental factors that constrain an individual's attempt to maximize fitness. As a consequence, individuals develop behavioral strategies designed to solve a variety of recurrent adaptive problems set by nature.

Origins and Early History of the Field

Behavioral ecology is a relatively new discipline and, for the most part, it is practiced by anthropologists. The publication of E.O. Wilson's *Sociobiology* (1975) along with the earlier work of biosocial anthropologists such as Robin Fox and Lionel Tiger (Cronk, 1991) and, in particular, evolutionary biologist Richard Alexander (1974) were critical in stimulating interest in applying Darwinian approaches to the study of human behavioral diversity. Very quickly Wilson's sociobiological approach was found to be limiting because it was largely based on older ethological approaches which posited relatively simple, general, and rigid models of the relationship between genes and human behavior (Winterhalder and Smith, 1992: p. 9) (*see* Sociobiology: Overview; Sociobiology: History of). This was especially apparent in his final chapter of *Sociobiology* (1975: pp. 547–575) where he considered humans. For example, in that work Wilson suggested that certain behavioral traits such as territoriality among foraging peoples were universal (1975: pp. 564–565). This claim and the approach that generated it was shown to be limited in a paper by Dyson-Hudson and Smith (1978), a kind of approach commonly used today in behavioral ecology to understand human behavioral variation. Using a strategic cost-benefit model developed by the avian behavioral ecologist J. Brown, they showed that territoriality was variable among tribal populations and was determined by specific environmental factors consistent with evolutionary theory.

As will be more fully described later, environmental cost–benefit approaches in the context optimization and game theoretic models are at the core of much of behavioral ecology. It is vital to understand that behavioral ecology is a branch of evolutionary biology and the core of evolutionary biology is about changes in the frequencies of genes through time. However, behavioral ecology is agnostic about the causative role of genes in the study of human behavioral variation. This position was clarified by Alan Grafen (1984) with his notion of the phenotypic gambit. Phenotypic variation is shaped by an individual's genotype interacting with a variety of cultural, developmental, environmental, and other nongenetic factors. The degree to which variation in any trait is a consequence of genetic variation is not directly relevant to the formulation or evaluation of behavioral ecological models. This approach is consistent with analyses in nonhuman behavioral ecology (Alcock, 2005).

Relationship to Other Fields Using Evolutionary Approaches to the Study of Human Behavioral Variation

The field of evolutionary psychology (Buss, 2005) is often inaccurately equated with behavioral ecology. It is therefore critical to distinguish between these complementary Darwinian approaches to the study of human behavioral variation. Behavioral ecology attempts to develop hypotheses regarding variation in behavioral strategies that individuals employ to maximize their inclusive fitness. In some studies, the central focus is on the reproductive consequences of behavior. In contrast, evolutionary psychologists are interested in elucidating the cognitive mechanisms (or mental modules or cognitive architecture) that evolved in humans in the 'environment of evolutionary adaptedness'

(*see* Evolution of Cognition: An Adaptationist Perspective; Human Mate Choice, Evolution of). This approach stresses the fact that all adaptations are to historic environments and it is problematic to assume that traits that were adaptive in the past are adaptive in current environments. As a consequence, evolutionary psychologists seek to uncover mental modules that were designed by natural selection to solve problems such as: What criteria do people use to select mates? How does mate selection criteria differ between the sexes? Who are my kin? How are exchange relationships managed? From this perspective, the actual reproductive consequences of behavior are often of no immediate concern. Other differences distinguishing these fields include behavioral ecology's reliance on naturalistic fieldwork among tribal peoples in contrast to evolutionary psychology's questionnaire surveys and laboratory experiments typically with Western college students, and behavioral ecology's focus on relationship behavior and reproduction in contrast to evolutionary psychology's emphasis on evolved psychological mechanisms that induce behavior. However, behavioral ecologists are beginning to test evolutionary psychological models of mate selection models in nonwestern populations. For example, Marlowe (2004) examined male and female mate preferences among the hunting and gathering Hadza, discovering similarities but also some significance discordances between this population and modern people typically studied by evolutionary psychologists. Recent research on operational sex ratios and marriage markets (Pollet and Nettle, 2008) suggests that evolutionary psychologists' reliance on Trivers' ideas on sex differences in mate choice may require modification. A general critique of too great a reliance on westerners in evolutionary and general psychology research on basic psychological traits is the one by Henrich et al. (2010) emphasizing Marlowe's point about the limitations of research on a 'thin slice of humanity' otherwise known as undergraduate college students.

Multilevel selection (Wilson and Wilson, 2007) and dual inheritance theory (Boyd and Richerson, 1985; *see* Gene-Culture Coevolution) are of interest to some behavioral ecologists because both approaches rely on adaptationist theory. In multilevel selection, it is argued that selection can occur at a variety of biological levels (gene, individual, or group). This approach is of interest to some behavioral ecologists because of its potential to solve first- and second-order collective action problems in the study of cooperation, exchange, and coalitional strategies in warfare.

What is sometimes known as dual inheritance theory or gene-culture coevolution (Boyd and Richerson, 2005) is founded on the realization that cultural traits or memes are similar to genes because both are replicators that use vehicles (bodies or minds) to transmit themselves across generations through social learning 'biases' and are subject to selective forces. Cultural traits differ from genetic traits in their mode of transmission. Certain cultural traits may dominate a cultural pool because they directly enhance the fitness of an individual (e.g., use of spices for meat, see Billing and Sherman, 1998). On the other hand, cultural practices such as the use of fire for cooking (Wrangham et al., 1999) had an enormous impact on our entire digestive system leading to numerous genetic changes. Boyd and Richerson (2005) further propose there are psychological mechanisms such as the tendency to emulate high status people, or copy what the majority of individuals do that are designed by natural selection and crucial for the transmission of culture. In addition, cultural traits may be transmitted laterally within generations instead of lineally through generations allowing them to spread more rapidly. Compared to behavioral ecology and evolutionary psychology, dual inheritance models have only recently begun to be tested empirically, both in the lab using experimental methods similar to evolutionary psychology and in the field in similar populations as to those studied by human behavioral ecologists (*see* Cultural Evolution: Overview).

Relationship to Traditional Social and Behavioral Sciences

Behavioral ecology is distinguished from traditional anthropological and social science theory in its emphasis on the individual or gene as the unit of selection and the idea that much of the content of culture is a consequence of decisions by individuals to enhance their inclusive fitness. Ever since its founding as a discipline, anthropologists have argued that individuals sacrifice themselves to enhance the integration or survival of the social systems in which they participate or are much like puppets or robots manipulated by culture (Cronk, 1991). Furthermore, any attempt to reduce or link cultural behavior to lower levels of analysis such as psychology was specifically condemned. Human behavior was believed to have emergent properties irreducible to the facts of psychology and biology. While it is clear that some dimensions of human behavior are not usefully reduced to underlying psychological or biological processes, the ever-growing body of evidence discussed later tells us that humans are biological and psychological entities and many aspects of human behavioral diversity can be usefully linked to underlying levels of analysis.

Theoretical Armamentarium

Behavioral ecology is strongly informed by a series of theoretical breakthroughs developed in the early 1960s and 1970s in the evolutionary analysis of social and foraging behavior. These breakthroughs occurred in the context of optimization and game theoretic models that predict behavioral strategies consistent with fitness maximization under a variety of constraints. These include inclusive fitness (or kin selection, Hamilton, 1964), senescence (Williams, 1957), reciprocal altruism (Trivers, 1971), sexual selection and parental investment (Trivers, 1972), sex biasing in parental investment (Trivers and Willard, 1973), optimal foraging theory (OFT) (Winterhalder and Smith, 2000), and, most recently, life history theory (Stearns, 1992). These works clearly demonstrated that behavioral variation was an apt subject for investigation from an evolutionary perspective consistent with the modern synthesis and an individual centered view of evolution. As noted, some behavioral ecologists are closely examining the utility of multilevel and cultural selection, especially in the area of cooperation. Early on in the development of behavioral ecology there was an expectation that kin selection would inspire

considerable research especially in the areas of food exchange and other forms of cooperative behavior. As will be evident later on, few studies have made kin selection a central focus of investigation.

Areas of Application

Foraging Theory

The foraging strategies or the collection of wild resources has been a fundamental area of interest because of its implication for the structuring of socioeconomic relations between the sexes, parental investment, group size, and mobility patterns. One of the earliest applications of behavioral ecological research came with the application of OFT (Stephens and Krebs, 1986) in the study of hunting, fishing, and gathering (or foraging behavior) among modern hunter–gatherers and foraging horticulturalists. OFT allows researchers to develop fundamental hypotheses that predict which food resources foragers will pursue when encountered during a search (diet breadth), where foragers will travel to search for resources (patch choice models), and how long they will stay in patches before moving to other areas (marginal value theorem). These models assume that foragers have a goal to maximize their net rate of return while foraging. By doing so they are ultimately able to maximize their fitness. The rate of return is indexed by a currency such as calories or another attribute of food value (e.g., Hill, 1988). This assumption is reasonable because food resources are fundamental to survival and reproduction for one of two reasons. When the environment is poor, foragers are likely to be 'resource limited.' Therefore, maximizing one's net rate of return allows foragers to acquire the greatest amount of food while foraging. On the other hand, when the environment is relatively rich, foragers may be 'time limited' such that efficient acquisition of food resources leaves foragers with more time to engage in alternative fitness-enhancing activities such as childcare (Winterhalder and Smith, 2000).

A number of qualitative and quantitative tests of optimal foraging models have been applied to the problem of diet breadth (Hill and Kaplan, 1992). Qualitative tests predict directional tendencies in prey choice by showing that diet breadth (the number of different species that will be pursued upon encounter), for example, will expand or contract depending on the encounter rates of highly profitable species. Quantitative tests predict the precise number of species a forager will pursue under a variety of environmental conditions (Hill and Kaplan, 1992), which species will enter or drop out of the optimal diet breadth, and the exact rank-ordering of species in the diet breadth. To complicate matters, most studies of diet breadth show a sophisticated division of labor between men and women, and between children and adults (Hill and Kaplan, 1992), which seem to be based on game versus vegetable products for the former and skill and strength levels for the latter. Another constraint influencing diet breadth is pregnancy and dependent childcare for women. In addition, the acquisition of large game or difficult-to-acquire resources may be a means to signal mate value (Smith and Bliege Bird, 2000) as well as to provision the hunter's family.

Although OFT was designed to account for foraging behavior in animals and then later extended to human foraging, recent applications have been made with considerable success in the areas of the origins of agricultural and pastoral food production (Winterhalder and Smith, 2000) and in archaeology (Bird and O'Connell, 2006). It has also rekindled anthropological interest in the problem of conservation among native peoples. Thus far, research indicates that true conservation is rare among native peoples but even more importantly researchers are attempting to specify the conditions under which conservation is likely to emerge as an adaptive strategy (Hames, 2007).

Resource Transfers

The movement of goods, and, to some extent, services, between families and individuals has received considerable attention by behavioral ecologists. Traditionally, such research is subsumed under the terms of exchange or reciprocity (for an extensive review see Gurven, 2004). Behavioral ecologists term such activities transfers because it more neutrally characterizes resource movements between groups and/or individuals compared to traditional terms such as exchange or reciprocity (which assume that the transfer of goods or services between individuals will be returned in some material form at some point in time). In the analysis of transfers, one assumes that giving or yielding a resource that one has acquired will be done such that the owner of the resource gains something in return or avoids a cost in defending that resource. As a consequence, models of transfer assume that the benefits of giving are greater than the costs of monopolizing the resource. The models of transfer developed thus far include (1) scrounging (or tolerated theft); (2) risk minimization; (3) trade or exchange; and (4) costly signaling.

At one extreme, coercive models of scrounging or tolerated theft assume that the resource acquired cannot be easily or effectively defended against those who lack resources, and that the benefit of giving a portion of the resource presents a higher payoff than the cost of defending it against another who is in greater need and thus more willing to contest the resource. At the other extreme are models of sharing, which assume that individuals give resources to others contingent upon an expectation that something of value will be returned to the giver in the future. For example, when resources cannot be predictably acquired (especially true in hunting), risk minimization or pooling strategies are employed through the mechanism of reciprocal altruism. Individuals who acquire resources share with those who have been unlucky in the hunt with the expectation that in the future, should they return home without game, others who have acquired game will share with them. Kin selection models have been used to explain why resource transfers tend to be biased toward close kin; costly signaling (and sexual selection models) argue that actors attempt to acquire resources that require considerable skill to demonstrate their desirability as a mate or ally; and trade models suggest that transfer occurs through specialization via the mechanism of reciprocal altruism.

In collaboration with gene-culture coevolutionists and experimental economists, described earlier, a number of

behavioral ecologists have used experimental economics methods (e.g., dictator, ultimatum, and public goods games) to illuminate how culture and market integration affects patterns of cooperation and exchange (Henrich et al., 2005) across 15 different societies (*see* Human Cooperation, Evolution of). The comparative results indicate that the canonical model (maximizing selfishness) is incorrect in all societies. Instead there is considerable cross-cultural variation and much of the variation is explained by the degree of market integration and the importance of cooperation in daily life.

Marital Strategies

Most marital models are generally founded on Trivers' (1972) observations about mate selection whereby females seek good genes and/or male investment while males seek numerous mates with high reproductive value. Approaches are further informed by a variety of models ranging from the polygyny threshold model (Borgerhoff Mulder, 1990) and pathogen stress (Low, 1990) to male coercion (Marlowe, 2000) and socially imposed monogamy (Alexander, 1974). The polygyny threshold model predicts that females will select mates according to the quantity of resources they control. In short, wealthy males are much more likely to mate polygynously than poor males. In most cases, ownership of material resources (e.g., agricultural land or livestock) is what differentiates poor from wealthy men.

The polygyny threshold model assumes female choice in marital affairs. In many cases, this assumption is clearly suspect and male coercion or parental or kin control may determine a woman's marital fate. Equally troubling is the fact that in many cases female fertility declines under polygyny (especially true for junior wives) and monogamous women oftentimes have higher fertility. At this point, it is clear that polygyny will nearly always enhance a man's fertility but it frequently impairs that of a woman. This latter issue is leading researchers to seek factors that could compensate for lowered fertility. For example, it may be the case that although a woman may bear fewer offspring under polygyny she may bear an equal number of grandchildren as in the case of Mormon polygyny (Josephson, 1993). This would be true if her sons were polygynous, married earlier than average, or married women with high reproductive value.

Although polygyny is permitted in nearly three-quarters of all ethnographic populations, monogamy and the rare case of polyandry (a woman having more than one husband simultaneously) are being investigated through modified versions of the polygyny threshold model. In the case of monogamy it is becoming clear that extramarital mating, or special matings (e.g., concubinage in historic societies) and remarriage following divorce (serial monogamy) is more common among wealthy males. Although such systems are officially monogamous, from a reproductive point of view they produce the high male reproductive variance characteristic of polygynous systems. However, monogamy in many cases is ecologically imposed such that a single male may not have the resources to support more than one wife and in extreme cases difficult environments may lead to polyandry (Starkweather and Hames, 2012). Finally, the advent of the state and legal imposition of socially imposed monogamy is currently poorly understood because these systems often have extremes in male wealth that should lead to polygyny (Geary and Flinn, 2001).

However, in some societies where economic stratification is absent and men are unable to differentially control resources, some men are polygynous because they are exceptionally productive (e.g., excellent hunters) or have achieved political power or status (e.g., distinguished warriors, leaders, or shamans).

Reproduction: Parenting and Life History Strategies

Studies of parental effort have focused on the issues of birth spacing, differential investment in offspring, and the interaction between mating and parenting. The ornithologist Lack was the first to recognize the trade-off between offspring number and offspring quality (or the ability of offspring to thrive and eventually reproduce). Since parental resources are limited, more offspring, through a shortening of the birth interval, will mean less investment per offspring and the potential for reducing each offspring's fitness. This trade-off suggests that there will be an optimal number of offspring that maximizes a parent's fitness and this number will vary with environmental circumstances. In general, one would predict that where parental resources are abundant birth intervals should be short and where parental resources are scarce birth intervals should increase. The cross-cultural evidence from natural fertility traditional societies strongly supports the relationship between parental resources and reproductive success: wealthy parents or culturally successful parents have higher fertility than poor parents (Smith, 2004).

In a seminal article, Irons (1979) suggested that there ought to be a correlation between cultural and reproductive success. Cultural systems are structured so as to encourage individuals to achieve certain kinds of culturally valued statuses. These achievements vary culturally depending on local environmental constraints. Both in traditional and in a number of recent societies, which have not entered the most recent demographic transition, culturally valued statuses are achieved through hunting prowess, religious rank, herd ownership, political leadership, occupational status, or land holdings. At this point, there are more than 30 studies (Hopcroft, 2006) showing in nearly all cases a positive correlation between cultural achievement and fitness (either fertility or survivorship of offspring) or factors strongly associated with fitness (number of wives, frequency of extrapair copulations). However, it is very important to note that this relationship is demonstrated for male but not female reproductive success. Significantly, attributes that lead to high male fitness such as polygyny decrease female fitness at least over the short term but perhaps not the long term. However, the relationship between cultural and reproductive success does not appear to hold in the modern context which is addressed in the section 'Life history.'

Parental investment

In general the amount of investment an offspring receives from parents depends on (1) the relatedness between parent and

offspring; (2) the effect of investment on the offspring; and (3) the effect of investment on parents' future reproduction and survival. These hypotheses have been positively evaluated using cross-cultural and ethnographic cases studies (Daly and Wilson, 1984). For example, the probability of infanticide, abuse, and neglect has been shown to be strongly sensitive to these factors. Infants who are unrelated to a woman's current husband or who have congenital defect or who are born in times of economic privation or whose continued investment would harm the survivorship of older offspring receive little or no investment. The thinking explicit in this approach is that parents adjust their investment in children according to their perceptions of a child's quality, paternity, current environmental conditions, and the needs of other offspring. Further investigations into differential parental investment have been inspired by the Trivers and Willard (1973) model where sex of offspring may influence investment. This model predicts that mothers in good condition will invest more in the sex that has greatest variance in reproductive success (usually males) while mothers in poor condition will invest more in offspring with least reproductive variance (usually females). Research on societies as diverse as hunter–gatherers, pastoralists to eighteenth-century Germany and nineteenth-century India has demonstrated the predicted differential investment by sex and distortions in sex ratios. However, research in modern industrialized nations is not always consistent.

Parenting or mating effort?

Male economic activities, especially hunting, are conventionally seen as kinds of parental effort by males. However, we have long known that males frequently transfer resources to households other than their own. For some theorists, such behavior may be fruitfully viewed as costly signaling or attempts to create new mating relationships or acquire social allies (Smith and Bliege Bird, 2000). Essentially, males are attempting to display honest but costly signals of fitness to others.

Life history

Life history strategies deal with age-specific schedules of mortality and fecundity and the traits that are directly a result of these schedules (Hill and Kaplan, 1999: p. 397; Kaplan et al., 2000). It deals with fundamental developmental events such as age at first and last reproduction, growth rates, birth intervals, and senescence. The theory is based on the assumption that somatic effort (growth, development, and maintenance) and reproductive effort (e.g., mating and parenting) are negatively correlated. Formal research in this area is relatively new but rapidly developing and has focused on the peculiar human trait of menopause, timing of reproduction, and demographic transition theory.

The grandmother hypothesis attempts to explain the evolution of menopause, a life history trait that is nearly absent among mammals but well documented in humans. The model predicts that women will cease reproduction prior to death in order to ensure required investment in current dependent offspring and to assist their children in the rearing of grand offspring. Although attractive, the model does not, as yet, show that continued reproduction until death is not a superior alternative and does not account for longevity of reproductive potential in males (Peccei, 2001). However, it has generated considerable research on the role that grandmothers play in the survivorship and fertility of their kin (Sear and Ruth, 2008) and alloparenting or cooperative breeding (Kramer, 2010).

Throughout history, humans have passed through a number of demographic transitions beginning with a high mortality and high fertility regime to today's worldwide transition to a low mortality and low fertility regime. A central issue behavioral ecologists are confronting is the apparent paradox between fertility and wealth. In tribal and in many state-level historical populations, there is a consistent positive correlation between fertility and wealth. This means that the traditional human pattern was to convert wealth into reproduction. However, at the end of the twentieth century, there is a global tendency for parents to reduce reproduction when wealth increases. Several explanations are offered for this trend. The 'human capital' perspective notes that in the current environment there is an increased requirement of parental investment needed to make children competitive in a modern labor market where earning capacity is determined by parental investment in such things as education (Kaplan and Lancaster, 2010). Others would argue that low reproduction in the context of high wealth is a consequence of a changed environment: for the first time in human history, we possess safe and effective means of contraception, an innovation that humans did not previously possess. This has led to research demonstrating that there is a kind of correlation between wealth and reproductive success, at least for men (Hopcroft, 2006). This research shows that wealthy men have greater numbers of premarital and extramarital unions than poor men (Perusse, 1993). This lends some credence to the perspective that some of the adaptations we currently possess cannot always be understood by looking at the reproductive consequences of behavior.

Summary

Human behavioral ecology is a young and explicitly Darwinian approach to the study of human behavioral variation. It redresses an absence of evolutionary considerations in the analysis of human behavior and social organization in the social and behavioral sciences. Since its inception in the late 1970s it has spawned the development of new journals and academic specialties explicitly devoted to training students to query the evolutionary bases of behavior. Its penetration into academic life has been uneven. It is most prominent in those disciplines such as anthropology and psychology where human evolution is considered relevant for a holistic understanding of human behavior or in economics where self-interest, methodological individualism, and maximization are key elements in modeling behavior. It has been resisted in disciplines such as sociology and political science where findings on human evolution are either ignored or, at best, regarded as irrelevant.

Abstract

Investigations from diverse domains of study – from developmental and comparative psychology to developmental biology, evolutionary theory, and paleoarchaeology – have been converging to offer a fresh understanding of the evolution of modern human cognition. This emerging picture suggests that our hominid ancestors engaged in complex forms of cooperative social processes and protocultural practices and that *Homo sapiens* evolved in relation to the functional opportunities afforded by these background ecological conditions. Particularly significant is the emergence of processes supporting the cross-generational transmission of information during ontogeny and the pedagogical and technical means to preserve the knowledge gains of prior generations.

Introduction

Scientific inquiry into the evolution of modern human cognition continues to be entangled in centuries' long nativism–empiricism debates from epistemology. In the wake of the nineteenth- and twentieth-century developments in science and technology, these alternatives have taken on distinctive forms. Nativism has been naturalized by being grounded in an individual's genetic endowment, which reflects outcomes of natural selection processes once operating on the species. Empiricism has shed any allusion to a blank slate, if it ever did hold such a view (even John Locke assumed some characteristic ways in which the mind operates). Today, all camps agree that biological and experiential factors play crucial, contributory roles in the ontogenesis of human cognition. However, this appearance of partial unanimity should not mask the striking, underlying legacy of differences that persists.

Over the past half century, nativism in psychology – which previously had been mired in imprecise and largely descriptive instinct theories – received a fresh boost from Chomsky's treatment of language as an innate biological endowment, operating independently of other cognitive functions, and requiring minimal environmental input to set in motion. This nativist approach to language prompted others to propose a wide-ranging set of innate, modularized cognitive functions that account for the varied, reasoning-like cognitive operations of the human mind. These modules are viewed as being grounded in encapsulated, brain processes that are products of selection over phylogenesis. Although these nascent functions are 'triggered' by environmental circumstances, their specific character is not acquired (learned). In some circles, these functions are conceptualized as computational processes operating on symbolic, mental representations of the environment and of thought. As a shorthand, the author will refer to this group of approaches, as some adherents refer to themselves, as *neo-nativist*. Neo-nativist proposals are located at the convergence of several twentieth-century developments: psycholinguistics, neo-Darwinian population biology (the synthesis of Darwinian selection and genetics), computer and cognitive science, as well as certain strains of comparative psychology and ethology.

In contrast, an alternative line of thought has emerged over this same time period, although its roots can be traced back to earlier efforts in developmental biology and embryology (Gottlieb, 1992). This alternative shares the empiricist emphasis on the environmental context for developing psychological processes, but is otherwise quite different from that lineage. For convenience, this approach will be referred to here as *transactionist*. The principal differences between standard empiricist approaches and transactionist approaches rest on their conceptualization of the organism. Empiricist approaches have tended historically to assume that the organism is a relatively passive recipient of the press of environmental circumstances, whereas transactionist views emphasize the active character of organismic functioning and the reciprocal, mutually constituting nature of environment–organism relations over time. From the standard empiricist approach, the individual may be sensitive, and even responsive, to contingent relations among, for example, patterns of stimulation; however, psychological processes do not contribute in any substantive way to the character of those relations. Transactionism emphasizes that, with few exceptions, organisms are active *participants* in animal–environment systems (Gottlieb, 2003; Oyama, 1985; Thelen and Smith, 1996). A transactionist treatment of the evolution of modern human cognition grows, in part, from developmental biology and the confluence of ecological psychology, embodied cognition, dynamical systems thinking, and evidence from paleoarcheology.

Undeniably, neo-nativist approaches give considerable attention to the environment, but most substantively with regard to its role in phylogenesis. Grounded as these approaches are in neo-Darwinian thinking, it is ancestral environments rather than contemporary conditions and their influence on ontogenesis that are accorded central importance. From a neo-nativist perspective, experience over ontogeny serves as an overlay to the expression of innate structures. There is a body of research that would seem to be consistent with neo-nativist claims of innate, modularized cognitive functions appearing as early as 3 months (e.g., Carey, 2009; Spelke and Kinzler, 2009). However, this line of research is faced with the seemingly irresolvable challenge of how to assess infant knowledge prior to any postnatal experience. Also related to

this challenge is the problematic nature of the very concept of the innate or instinctive, which has been the target of considerable criticism by behavioral biologists for over half a century (e.g., Hailman, 1969; Lehrman, 1953). In addition, evidence has shown that some of the neo-nativist laboratory findings are highly dependent on the specific testing conditions employed (e.g., Learmonth et al., 2002; Thelen and Smith, 1996). From a transactionist perspective, the neo-nativist stance is judged to overlook the constitutive role that current environmental structures and sociocultural–historical processes play in ontogenetic development. Related to these points, nativist approaches are criticized for failing to recognize the ongoing role of the individual and the group in shaping environmental influences. Obviously, these are contentious issues between the two camps. For brevity, this essay primarily focuses on features of a transactionist approach.

Hominidae

Perhaps the major challenge facing any attempt to understand the evolution of modern human cognition is the absence of other extant species within the genus *Homo* besides us. For this reason, one must turn to two sources of comparative evidence: (1) other living genera of the Hominidae family: *Pongo* (orangutans), *Gorilla*, and *Pan* (chimpanzee) and (2) paleontological and archaeological remains of ancestral species within the *Homo* lineage. There are obstacles to be faced in pursuing either line of investigation. On the one hand, comparisons with other living primates must be tempered by the recognition that the common ancestor to these lineages is estimated to have existed roughly 6 My. The very long stretches of time over which these lineages have been evolving separately should be borne in mind. In the case of the paleontological and archaeological record, on the other hand, evidence can be difficult to come by. Only the most durable traces remain in the face of the assaults of time. Moreover, the identification and sequencing of distinct prior species is quite fluid. The number of identified species of *Homo* has been growing with each decade – there are minimally 20 at present – and the evidence continues to accumulate and prior findings reevaluated in light of them. Still, it is clear that a view that human evolution was a linear succession of species can no longer be sustained.

When modern humans are compared with chimps and bonobos, striking similarities are found and also differences. The differences are particularly intriguing because of the apparently high degree of genotypic similarity between these species. Among the most obvious psychological differences between humans as compared to apes are several qualities: greater complexity and variation in patterns of social interaction and cooperation among humans and the extended period of postnatal neurological immaturity and plasticity in humans, particularly in the first years of life. As it will be seen, these two qualities are related. Impressive indications of cooperation have been observed among nonhuman primates, both in the field and in the laboratory, especially with regard to hunting, defense, and problem solving generally. However, the patterns of cooperation that arise within the functioning of human social groups, including participation in sociocultural structures, symbolic means of engaging the world, and the greater potential to plan prospectively, give rise to possibilities that far outstrip what is seen among nonhuman primates.

Before further considering the functional possibilities that arise out of human social interaction, one must first face up to the challenge that cooperation generally poses for standard accounts of evolution. The challenge is that cooperative actions typically appear to incur costs to the actor, and for this reason, they would appear to run counter to the Darwinian assumption that individuals function to maximize their reproductive success. As such, an individual's actions that do not contribute to his or her own reproductive success, and the innate structures in which those actions are grounded will not be sustained over time in the population as a matter of course. Part of the conceptual challenge here is the neo-Darwinian assumption, which has dominated evolutionary thinking in biology and psychology for decades, that selection processes operate only at the level of the individual, or reducing the focus of selection to even a more microlevel, to the genes. Attempts to reconcile cooperation and self-interest at the level of individual selection have taken two forms: inclusive reproductive fitness or kin selection (promoting the reproductive success of individuals with similar genotypes) and reciprocity (actions that may produce short-term losses but with the expectation of long-term positive gains from others).

Of late, continuing debates over the limitations of these preceding claims have led to reconsideration of the possibility that selection operating simultaneously at multiple levels, including that of the group (posited earlier by Darwin in *The Descent of Man*), may be more robust grounds for explaining cooperative actions than neo-Darwinian explanations (Sober and Wilson, 1998). If individuals within a group on average benefit from cooperative processes, and if cooperation contributes to the longevity of the group and as a consequence, the reproductive success of sufficient numbers of individuals, then cooperation among individuals could be selected for and sustained over time at the group level. Notable has been the recent embrace of this viewpoint by one of the most prominent early advocates of the inclusive fitness view (Wilson, 2012). This emphasis on group selection poses significant challenges to the Neo-Darwinian point of view that has long held sway in psychology, principally in the hands of the so-called evolutionary psychologists. Importantly, as it will be seen, inclusion of group selection as a consideration regarding cooperative behavior is consistent with shifting views on the nature of infant development in psychology.

Intersubjectivity

Western conceptions of child development have long adopted the view that development is largely an individual journey and that the social aspects of development only assume a significant place beyond the first year once certain cognitive foundations are established by the individual and, in turn, symbolic thought begins to develop. Neither is this view no longer tenable empirically, nor is the tacit assumption – a remnant of outmoded 'faculty psychologies' – that social and cognitive development is separable. Beginning with research in the 1960s, it has become clear that human infants are remarkably

responsive toward other persons. Attention is directed more toward humanlike facial patterns than toward other features in the surround, particularly if those patterns are in motion. Further, cases of imitation by neonates have been reported in recent decades, although not without some challenge. Even by the most conservative interpretation, however, it is clear that to the extent that neonates can control their direction of gaze, they attend especially to social others, or at least humanlike visual patterns. Moreover, recent evidence indicates that throughout the first months, there is a growing attunement to the actions and even intentions of others that are directed toward the self (Reddy et al., 2013).

Often, findings such as these have been taken to indicate a preparedness for facial patterns per se, without viewing this sensitivity in a wider context that cuts across time-worn separate psychological domains. Attention (cognition) to faces is inseparable from attention to information of a social nature and ultimately an interpersonal nature. Specifically, these actions have been viewed by some researchers as evidence for the beginnings of 'intersubjectivity,' which refers to behavior that suggests the establishing of mutual awareness or attention between individuals, at least for brief intervals. Importantly, beginning around 6 months of age, mutual attention broadens such that infants begin to demonstrate sensitivity to the direction of another's gaze and to pointing, and by 12 months, such joint attention is commonplace among human infants. Notably, joint attention appears to be unique among humans. Although a few marginal cases of joint attention have been reported with laboratory-reared primates, it has not yet been observed in the wild. Whereas a wide range of animals, including birds and nonhuman primates, clearly learn about features of the environment through observing the actions of conspecifics, and in addition, adults of some species have been found to leave materials about for the young to practice manipulating (e.g., in the support of nest building), joint attention and intersubjectivity seem to be nearly unique human phenomena.

This capacity for establishing mutual awareness is a momentous step in human cognitive evolution because with its emergence, the infant's attention can be guided by the actions of more experienced individuals to particular environmental features. The significance of such human intersubjective processes for learning and development cannot be overstated; it underwrites all forms of pedagogy – the intentional transmission of information between generations. Broadly considered, it is the foundation for a great deal that transpires cognitively in ontogeny as well as for cultural evolution and cross-generational teaching. This claim is consistent with the findings that infants and children who have difficulties establishing or maintaining intersubjective processes face enculturation difficulties.

Hominin Evolution

The findings in support of the early social nature of infant functioning converge with the picture of hominin evolution that has been emerging over the past several decades. Cultural processes among hominin did not begin with the appearance of *Homo sapiens*. Paleoarchaeological evidence has revealed the establishment of semipermanent settlements beginning most likely with *Homo habilis* (2.3–1.6 My), and clearly with the appearance of *Homo erectus* (1.8 My). Such evidence indicates that at this point in their evolution, hominins were intensely social in ways not seen among extant nonhuman primates. (Cole and Hatano, 2007; Megarry, 1995).

The construction and maintenance of even the most basic settlement arrangements require a combination of foresight and interpersonal awareness as well as a rich degree of communication that distinguishes the hominid line at this juncture of evolution (Sterelny, 2003). The evidence for extensive migration by *H. erectus* and *H. sapiens* further suggests advanced patterns of cooperative behavior, communication, and planning. Wide dispersal through migrations by *H. sapiens* and *Homo neanderthalensis* is not seen among the other genera of the Hominidae family.

Evidence for semipermanent settlements and migration coincides with the findings of positive correlations between the size of the neocortex and group size among primates. Extrapolating this relationship to humans, Dunbar (1995) estimated that human social groups would not exceed 150 individuals and that prediction seems to hold up in comparative assessments of human societies. This is not to say that recognition of others would be limited to that number; indeed, human memory for faces has been found to be prodigious. Rather, this number points to a threshold for possessing sufficient knowledge of others and for self-monitoring to maintain interpersonal, cooperative relationships at the scale of communities. It seems likely that increased neocortical size and community size may have coevolved. As social groups become larger, more possibilities for cooperation and collaboration driven by enhanced prefrontal executive processes can result. Group success relative to other groups would favor those individuals who could function cooperatively in communities. As noted, human social groups historically were rather dispersed geographically, and for this reason, the 'ways of the group' were likely to vary due to local conditions and social history. Individuals would benefit from prolonged early periods of neurological plasticity in order to learn the ways of the specific group into which they were born.

Toolmaking

The archeological record of changes in toolmaking also points to the critical relationship between social and cognitive processes and to the role that pedagogy likely played in the appearance of early cultural processes. Taken broadly, a tool is any material feature of the environment used by an animal to mediate its engagement with other features of the environment. Working from this definition, many organisms are tool users. For example, chimps have often been observed utilizing a branch as a probe in a termite hill or a leaf as a vessel for transporting water to the mouth, elephants use branches as switches to swat insects, dolphins make use of sponges to harvest crustaceans from the sea floor, and some birds employ pine needles to probe bark for grubs. However, the modification of material features for the purpose of tool use is far less common. Tool construction requires considerable foresight (executive control) because the individual is operating to

realize some affordance that does not presently exist. In addition to tool construction, another distinguishing feature of advances in tool use is innovation. The animal must recognize that some feature has the potential for serving as a tool with the appropriate modification. In such cases, the animal needs to be attentive to the feature's dual affordance character: that once modified it can be wielded or otherwise manipulated by the individual and that it is suitable for the task in question (van Leeuwen et al., 1994).

Critical for the present discussion is the manner in which knowledge of tool use and tool construction is transmitted between generations. Research among primates has shown that the young of a species must have the opportunity to observe tool use by others and also have the resources for tool use available to them. With humans, the possibilities for transmitting information are greatly expanded by means of joint attention and guided participation, and later language, allowing for demonstration and instruction. In short, master–apprentice relationships that require intentional instruction are only possible on the back of these uniquely human functions.

When examining the evidence for early toolmaking by hominins, researchers are limited to those materials that can withstand the effects of time. For this reason, our knowledge of early hominin tool use and manufacture is limited primarily to stone implements and shells. Hides, sinews, and later, even fabric may well have been used extensively, but only in exceptional cases of preservation will such materials be found. Nonhuman primates have most likely been using selected rocks to, for example, crack nuts for millennia, and there is little reason to assume that these actions have changed over time. Evidence of stone toolmaking has been found only in the proximity of hominin remains or settlements. The pattern that is revealed in the record of stone tools over time among hominids is marked by very long periods of design stability, followed by small innovations that are preserved for considerable durations and then followed by a period of rapid innovation and change that continues to the present day.

The earliest manufactured stone tools have single chipped edges and have been dated at 2.7 My. The design was remarkably stable, spanning roughly 1 My. These artifacts (Oldowan tools) have been attributed to *Australopithecus garhi*, and were later produced by *H. habilis* (Mithen, 1996). In spite of the primitive appearance of these tools, their production requires some technical skill and foresight. The technique is commonly referred to as stone knapping, and it involves utilizing one rock as a percussor to chip away at another, less dense rock, calving off stone flakes in order to leave behind a sharp edge (Roux and Bril, 2005). Single-edged stone tools can be used for cutting, scraping, or gouging. These percussive actions are not random, but rather must be controlled as to force, angle, and location in order to produce a conchoidal fracturing of the implement. The production of these artifacts suggests a degree of executive control over motor functions yet to be found in nonhuman primates. It has been proposed that these skills point to cortical reorganization involving extensive neural connections between the prefrontal and cerebellar regions (Donald, 2001).

Further, production of this type of artifact necessitates an understanding of materials including the probable patterns of fracture of particular rocks. It is most unlikely that the skills associated with these techniques could be acquired through mere imitation. The complexity of the process and, significantly, its stability of production point to intentional instruction from artisan to learner along the lines of joint attention and guided instruction as described above. In short, these rather simple appearing implements index a major cognitive shift in hominid evolution: a new mode of deliberative information transmission across generations (Tomasello, 2001). At the same time, the recurrence of these patterns of production over vast stretches of time points to limitations in innovation and invention, or alternatively, the difficulty of preserving innovation across generations. In this regard, the cumulative results of innovation crucially depend on the possibilities of preserving through social transmission the gains of prior generations (Tomasello's 'ratchet effect'). Finally, the materials utilized in toolmaking have sometimes been traced to locations at a distance from where they have been found, suggesting an impressive level of deliberate planning rather than the fortuitous use of found materials. All these characteristics of even such relatively simple tools point to notable cognitive advances associated with increased cortical size in the hominin lineage.

The production and utilization of double-edged, quasi-symmetrical, chipped rocks with sharp points (Acheulean tools), which are attributed to *H. erectus*, begin to appear between 1.7 and 0.25 My (Abramiuk, 2012). These bifacial tools can be utilized for a far wider range of purposes than their unifacial predecessors. Designs varied in width and length, adapted for various tasks. Clearly, such tools require a greater degree of skill and planning yet seen, pointing to advances in planning with particular ends and purposes in mind, an understanding of materials, and the operation of pedagogy that permits the social transmission of the considerable know-how needed to produce these artifacts. This evidence points to the collaborative synergy of cognitive, motor, and social functions.

Symbolic Cognition

Communication, for present purposes, refers to the intentional sharing of information between individuals. (Obviously, communication from a cross-species perspective has a much broader and varied definition.) Fundamentally, it is a means by which one individual directs the attention of another to a feature of the environment or, later in development, to an abstraction such as an idea. Pointing is perhaps the most basic gestural form of interpersonal communication, and, as discussed above, it requires establishing an intersubjective relation (mutual awareness) among individuals.

Symbolic forms of intentional communication typically involve the utilization of auditory and visual patterns whose meaning is based on a conventional relationship between the symbol and its referent. In short, there must be a common understanding among interlocutors – from merely two individuals to a society to a global network – as to what an auditory or visual pattern refers. In turn, referential meanings reside in a shared semantic network which, as a matter of course, will require considerable exposure to discern. The capacity to

engage in symbolic communication in the form of an oral language or gesture appears to be universal, stemming at least in part (see below) from our phylogenetic history. Other forms of communication, such as pictures and written language, also depend on a symbolic capacity, and yet these forms derive from particular sociocultural histories and, hence, may not necessarily be universal. In general, symbolic thought comes to mediate most activities of a sociocultural nature. Theoretical traditions that emphasize the central role of activity in knowing (e.g., Vygotskian approaches) claim that what begins as interpersonal symbolic communication eventually becomes internalized and serves as the basis for intrapersonal symbolic thought. The emergence of symbolic communication broadly is tied to phylogenetic changes in the neocortex, as well as enhanced possibilities for early neuroplasticity (see, Deacon, 1997; Donald, 2001).

Much uncertainty shrouds the evolutionary transition from gestural communication along the lines of pointing to symbolic communication. The gap between these two forms of communication seems considerable. In the absence of other extant species of *Homo*, the transition from gesture to symbol may not be as apparent as it otherwise might be (Donald, 2001). However, vestiges of an intermediate form of communication can still be seen among modern humans, and occasionally isolated in some neurological cases, in the form of nonverbal, mimetic (meaningful) expression. Gesture is an integral part of human oral communication as a complement to speech (Goldin-Meadow, 2003), and it can also function alone as a symbolic form of communication, often of an iconic character, by representing, for example, some action or some feeling. Mimetic gesture can substitute for speech when interlocutors do not share a common language, and when circumstances are not conducive for communicating verbally. Notably, mimetic gesture can readily be seen in most cultures where traditional ritualized actions (e.g., religious practices) continue to function even in the midst of oral and written language. Donald speculates that mimetic (nonverbal) expression is a phase of communication that separately operated prior to oral language, and has subsequently been enfolded phylogenetically into communication functions generally. The continuing presence of mimetic expression offers the tantalizing hypothesis that the capacity to think symbolically evolved gradually, with mimesis being a crucial early step. Recent research on embodied meaning (e.g., Glenberg and Kaschak, 2002) and on the relationship between gesture and thinking (e.g., Goldin-Meadow and Beilock, 2010) aligns with this hypothesis.

Still, the question remains as to the ontogenesis of symbolic communication and of language more widely. Research by Goldin-Meadow et al. (2007) demonstrates the invention of idiosyncratic gestural communication (mimetic expression) among a sample of infants who are deaf siblings. These findings suggest that the rudiments of expressive actions at least do not require much in the way of environmental priming. Can the same be said of spoken language? The identification of common syntactic structures seemingly at work even across very diverse languages pointed to the possibility of innate brain structures (a 'language acquisition device') that have arisen through phylogenesis. These claims, which were accompanied by a barrage of arguments against the alternative possibility that language development could possibly proceed through learning and conditioning, left few cogent alternative accounts of language development for decades. But new possibilities have started to emerge that not so much undermine the evolutionary roots of language, but rather shift its emphasis somewhat by not losing sight of the fact that *H. sapiens* are fundamentally sociocultural, biological beings.

The Human Eco-niche

The expression 'ecological niche' (or eco-niche) is typically employed to refer to the subset of features and resources in a given locale in relation to which an animal carries out its daily activities. The standard use of eco-niche carries with it a presupposition that the organisms must fit adaptively 'into' their eco-niche. From this vantage point, adaptation is viewed as the organism's efforts to 'answer' a functional problem posed by the environment. In an influential paper, Lewontin (1978) argued that this conceptualization of adaptation, and the unidirectional view of environment–organism relations it conveys, is exceedingly narrow in its failure to recognize – as Darwin (1881) demonstrated in his final book – that organisms commonly alter their surrounds in order to better function in them. In recent years, this notion of 'niche construction' has received considerable attention in large measure due to the work of Odling-Smee et al. (2003), who have documented the ubiquitous character of niche construction across living organisms, from microorganisms and plants to animals. Living organisms alter their surrounds to varying degrees, and these actions play a *constituent* role in the fashioning and maintenance of their eco-niche. Moreover, such actions can, in some cases, alter environmental selection pressures and over time, resulting in shifts in the genotypic makeup of the population. In this way, actions of organisms can at times be at the leading edge of phylogenetic change.

Because niche construction is so commonplace in nature, it is no longer viable to claim, as once was the case, that what distinguishes hominins from other living things is the fact that they alter their environment (*Homo faber*). Nor are hominins to be distinguished by the *extent* to which they do so. Insects surely are the winners there. Instead, what is distinctive is the manner in which the fashioning of the environment through daily actions, and cumulatively over historical time, has come to play an essential role in supporting and shaping the ontogenetic development of humans as social beings.

Although ontogenetic development occurs in relation to some enduring properties of environments (e.g., a gravitational field), it also does so in relation to repeating patterns of activity among the individual's group. Particular patterns of group function typically stem from a cumulative history of addressing local challenges and, to a lesser extent, from the infusion of influences from external sources. An extended period of neurological and behavioral immaturity among infants and children affords opportunities for extensive discovery and learning from others, particularly with the scaffolding from intentional, guided teaching. Significantly, given this extended period of immaturity in humans, the actions of others in

structuring the developmental environment (niche construction) become especially crucial. What is found among newborns is considerable flexibility in adopting the ways of living that are specific to their social group, and in turn the development of skills though pedagogy (e.g., literacy) for retaining the knowledge gains of previous generations. Further, the learning of rituals, traditions, and social norms promotes group cohesiveness.

Such an emphasis on the essential role of the human eco-niche in ontogeny has reopened the debate on language origins as well as the development of other modes of cognition. Claims of innateness in cognitive abilities can be reevaluated by recognizing that biological processes at all points of development and to varying degrees are context sensitive. Contextual influences are among the *constitutive factors* in ontogenetic development, and human development in particular (Blumberg, 2005; Oyama, 1985). For this reason, ongoing investigative attention needs to be directed at contexts for development.

We are beginning to learn that infants are exquisitely sensitive to regularities in visual events and in the auditory stream (Aslin et al., 1999). Growing evidence, for example, is pointing to infants' sensitivity to the statistical regularities present in infant-directed speech (Saffran, 2003). It is an intriguing possibility that forms of infant-directed speech, indeed, even the structure of human languages themselves, might have emerged pragmatically from sociocultural practices over millennia as human societies discovered effective ways to make linguistic information available to be discovered by each generation (Deacon, 1997). Such practices surely would be shaped by constraints in human ways of functioning, reflecting an organism–environment mutuality that characterizes ecosystem processes generally. The possibility for acquiring language is species specific, no doubt. But the structure of language that seems to work most effectively, as well as the means of teaching it, may be the result of a slow process of sociocultural discovery. Variation in paths of development, in contrast, may reflect practices that have arisen in relation to particular local circumstances and that have proven to be effective for enculturation to the ways of the group. The view that emerges is an on-going, synergistic, coevolution of ecological structures and cognitive possibilities over multiple time scales.

Likewise, synergistic processes could be operating in the case of less canalized forms of cognition in tandem with the development of techniques and tools for thinking. Literacy emerged as a sociocultural practice, and we are still in the process of discovering ways to facilitate the development of its requisite skills. Similarly, techniques for representing spatial relationships (e.g., maps) are cultural innovations, and efforts to enhance the utilization of these representations are ongoing (Uttal et al., 2013). The latter two examples also point to a significant shift in cognitive possibilities among humans, namely, the development of tools that have the effect of distributing task demands across the individual–artifact relation (Clark, 2008). Specifically, the creation of symbolic notation for the means of keeping records has allowed individuals and societies (e.g., Connerton, 1989) to expand memory in the form of written or graphic records. Moreover, problem-solving capacities can be enhanced by using a display of information, such as calculations on paper, as a 'work space' for cognitive tasks (Wilson, 2004).

The pace of cultural change has been accelerating, and with it the cognitive changes needed for living in an increasingly complex world in a sustainable manner. The recent development of electronic global communication networks is yet another reflection of the enduring tendency for all animals to transform their eco-niche. However, the far-reaching nature of these changes has few parallels in human history, comparable perhaps only to the invention of writing, mathematics, and time. Its influence on the continuing evolution of human cognitions is barely visible on the horizon.

Abstract

Human cooperation is a novel evolutionary puzzle because we cooperate with genetically unrelated individuals in groups that comprise millions of people. Direct reciprocity, especially when considering errors in behavior, has shed light on pairwise cooperation among well-known but genetically unrelated people. Three mechanisms have been identified to explain large-scale cooperation in humans. Cooperation can evolve by indirect reciprocity in groups as long as people can observe each other's behavior, or can garner honest information via gossip on who cooperates and defects in their interactions. Humans also have a disposition to cooperate and to punish those who do not, even at a cost to oneself, and such costly punishment can sustain cooperation in even larger groups of people who do not know much about each other. Cultural group selection explains the scale of human cooperation, why it is variable, and why norms enforced by sanctions are group-beneficial. Support for these theories has come from laboratory experiments using a variety of behavioral economic games, and from field studies in small-scale societies. Key open questions include understanding what characterizes goodness in indirect reciprocity, why gossip is sufficiently accurate, and why people are motivated to engage in costly punishment.

Introduction

Humans are much more cooperative than any other vertebrate species. Division of labor and delayed exchange of valuable commodities occurs in virtually every human society. The sick and injured are fed and cared for. Public capital facilities like communal shelters, ceremonial grounds, and defenses are commonplace in human societies. Such cooperation is virtually absent in other vertebrates. Humans even help strangers – donate blood, give directions, offer their seat, engage in philanthropy – more than most other vertebrates help individuals they have known their entire life. Language too is a low-cost signaling system, made possible because cooperation ensures that communication is sufficiently honest. Vertebrates that do not cooperate are limited to costly, self-verification of signals.

This high degree of cooperation makes humans an ultra-social species. Ultrasociality is rare in nature because of the detrimental effect of free riders – individuals who take the benefits of cooperation without paying the cost. Nonetheless when ultrasociality does occur, it has spectacular ecological consequences. Two eusocial taxa – ants and termites – make up one-third of the terrestrial animal biomass of the planet. Humans have higher biomass than any terrestrial mammal aside from the domestic cows we use in farming. Thus, if the free rider problem is solved, there are tremendous evolutionary gains to be had from cooperation.

Human ultrasociality is a novel evolutionary puzzle because it is not explained by genetic relatedness. Most ultrasociality in nature occurs among genetically related individuals (Smith and Szathmary, 2000). In multicellular organisms, cells are clones. In eusocial insects, workers tend to be siblings. But humans cooperate in groups comprised of hundreds, thousands, and even millions of genetically unrelated individuals. A growing body of research suggests that our extreme reliance on culture – socially transmitted knowledge, beliefs, and norms – might be the key ingredient that fueled this transition (Richerson and Boyd, 2005; Henrich and Henrich, 2007; Bowles and Gintis, 2011). Piecing together this puzzle has illuminated a diverse range of human phenomena such as our proclivity to punish wrong doers, our attention to fairness, laws and norms, morality and justice, and our penchant for gossip.

How Do We Know That Humans Are Cooperative?

Key insights on human cooperation have come from economic experiments, which have demonstrated that people all over the world violate the assumption that humans have purely self-interested preferences (J. Henrich et al., 2004; Camerer, 2003). In the Ultimatum Game, two anonymous players get to divide a sum of money. The proposer offers a division. If the responder accepts the offer, the two players get their proposed shares. If the responder rejects, they both receive nothing. If people are money-maximizers the lowest possible offer will be made and any offer will be accepted. Another game commonly used is the dictator game. Here the experimenter gives one of the players – the dictator – a sum of money. The dictator can either keep all of it for herself, or give some to the second player – the recipient. If players are money-maximizers, dictators will keep their full endowment. A third game is the public goods game. Here a group of participants are given a sum of money. They may contribute a portion of this endowment to a common pool, which is multiplied by the experimenter and divided equally among players regardless of their personal contribution. The multiplication factor is set so that a player can maximize her income by not contributing anything. In a seminal study Henrich et al. (Henrich et al., 2005) conducted these three experiments across 15 nonindustrialized societies including mobile hunter-gatherers, small-scale horticulturalists, acephalous pastoralists, and agriculturalists. People behaved quite differently in different societies, but in no society was their behavior consistent with money-maximization. Proposers offered more than the minimum possible amount, responders in many societies rejected low offers, dictators transferred money to the recipient, and participants contributed to the common pool.

Research on contemporary small-scale foragers also paints a picture of societies that are remarkably cooperative. Among the Shiwar, a forager-horticulturalist society in South America, more than 50% of adult men had disabilities that kept them from foraging for more than a month (Sugiyama, 2004). In any other vertebrate society, such a lengthy disability would mean death. Human foragers instead regularly survive these periods because others provide for them during such times. An analysis of the Hiwi and Ache, two forager societies in South America suggest that there is extensive food sharing beyond the household (Gurven, 2004). Among the Hiwi, in more than 75% of the foraging events, some amount of food was given to another household. In about 15% of foraging events, 90–100% of the food acquired is given to another household.

The human life history itself would be impossible without intensive cooperation, so much so that humans are considered to be cooperative breeders (Hrdy, 2009; Hill and Hurtado, 2009). Compared to the typical primate, humans invest in higher quality offspring. Human offspring take longer to reach sexual maturity and become self-sufficient foragers only by their late teens, but they have larger brains and longer lifespan. One would expect that such prolonged care of offspring would require longer inter-birth intervals – the usual pattern observed in mammals whereby quality comes at the expense of quantity. But surprisingly humans have higher fertility and shorter inter-birth intervals than chimpanzees, even though chimpanzee juveniles need no care. In a synthetic review of human life history traits, Kaplan et al. (2000) posit that food transfers are at the nexus of our escape from this trade-off. Post-reproductive women and adult males produce more food than they consume. Reproductive women and children produce less than they consume. Food transfers from these net-producers to these net-consumers allow reproductive aged women to support multiple dependent offspring at a time, and allow children to stay dependent for long.

Property rights are omnipresent in human societies of all types, from hunter-gatherers to nation states. There are tremendous benefits to be had if community members do not steal each other's unguarded property. People would not have to constantly guard or fight for their property and can utilize this time in production. Cooperation of this form must have been present among Paleolithic foragers. People would be disinclined to create complex tools and technology that require time and effort now but would pay off later, if they could lose these items to predatory band members. Human males spend far less effort staying in close proximity to their mates for mate-guarding than do males of most other animals. Free of the need to always mate-guard, men can spend their day foraging separately from women, specializing in different foods than women do.

Why Is Cooperation an Evolutionary Puzzle?

If cooperation is beneficial, and organisms that cooperate are immensely ecologically successful, why does evolution seldom favor cooperation? To see why, consider the payoff structures that organisms may encounter in nature that creates opportunities to benefit from cooperation. The payoff structure is the cost and benefit for each of the actors, given their behavior and the behavior of their partner(s). In some forms of cooperation, individuals have no incentive to defect (i.e., to not cooperate) as long as their partner cooperates. Table 1 illustrates such a payoff structure, also referred to as a mutualism or coordination game. Here two foragers have the option of either finding small game on their own, or coordinating with each other to hunt larger game. Assume that if they attempt to hunt the larger prey on their own they will fail. As long as the two foragers can communicate that they are willing to coordinate their foraging attempt, they have no reason to hunt alone. Realizing the benefits of cooperation in this case is easy: mutually agree to cooperate.

Table 1 Mutualistic interaction

		Forager 1	
		Hunt alone	*Hunt together*
Forager 2	Hunt alone	7, 7	7, 0
	Hunt together	0, 7	10, 10

An illustration of mutualistic payoffs where as long as one player cooperates, it is in the best interest of the other player to cooperate.

Table 2 Prisoner's dilemma game

		Player 2 (acquired fish)	
Prisoner's dilemma payoff structure		*Keep fish*	*Share fish*
Player 1 (acquired tubers)	Keep tubers	7, 7	12, 5
	Share tubers	5, 12	10, 10

An illustration of payoffs in a prisoner's dilemma where it is in a player's best interest to defect, regardless of whether the other player cooperates or defects.

Problematically, in many of the opportunities for cooperation in nature, individuals have an incentive to defect even when their partner cooperates. Such payoff structures are best illustrated by the prisoner's dilemma game (Table 2). Here one forager has spent the day fishing and the other acquiring tubers. At the end of the day, they can eat what they have personally acquired or they can share a portion of their day's catch with each other. Assuming that their optimal daily diet is a mix of tuber and fish, their joint payoff is maximized if they both share. But, forager 1 is better off keeping her fish if her partner keeps the tubers, but also if her partner shares the tubers. Likewise for forager 1. Thus both foragers will keep their catch forgoing the big gains they as a pair could have had from cooperating. The *n*-person public goods game illustrates this tension for a group of people: the group maximizes its payoff if everyone contributes to the public good, but each person has a higher payoff if they take the benefit without paying the cost of producing the public good.

Cooperation in a prisoner's dilemma or public goods game presents an evolutionary puzzle. To obtain the benefits of cooperation individuals have to behave in a way that maximizes the pair's or group's payoff, not their own. Evolutionary pathways to cooperation identify mechanisms by which cooperators can end up with higher payoffs (and consequently higher fitness) than defectors despite this disadvantage.

The Evolution of Small-Scale Cooperation

Kin Selection

Kin selection (Hamilton, 1964) explains a wide range of cooperation that occurs in nature, and plays an important role

in human cooperation too. Altruistic behavior can evolve if individuals preferentially direct their behavior toward kin. This is because if a person carries the cooperative allele, her relatives are more likely than a random individual in the population to also possess the cooperative allele. This means that if individuals cooperate only with kin, cooperators will be more likely than defectors to also receive the benefits of cooperation. Such positive assortment allows cooperation to evolve.

Although nepotism is one aspect of human cooperation, it does not fully explain human cooperation. Nepotistic sentiments do exist. The meaning of the word – handing favors unfairly to relatives – illustrates the struggle to suppress this form of cooperation in order to organize cooperation at a larger scale. Food sharing in hunter-gatherers suggests that humans have evolved other pathways to cooperation that may often compete with our nepotistic motivations. A study among reservation-dwelling Ache of Paraguay (Gurven et al., 2001) shows that offspring, siblings and parents get a larger percentage of an individual's share of a resource item. However, close kin outside of the nuclear family like nieces, nephews, aunts, uncles and cousins receive less than what an unrelated band member receives. Another study conducted in the same population (Allen-Arave et al., 2008) show that foragers do not preferentially share with households that have their kin. Instead, foragers give away food to households that need food, and to households that have given them food in the past. Moreover, when there are disadvantages to cooperating with kin, humans are able to manage even high-stakes cooperation with nonkin. Among the Turkana, a nomadic pastoral society in East Africa, warriors venture on stealth missions with two to five other men, in which they plan to take cattle of neighboring ethnic groups. These missions can be risky, and the team needs to engage in a fire-fighting if detected. Although a high degree of cooperation and trust in one's companions is required, such teams are often comprised of age-mates and friends, not brothers. When I have enquired about this to Turkana participants I interviewed, they explain that one of the brothers needs to look after the herds, and that if the raiding party happen to be killed on this mission, a loss of two sons would be catastrophic for a family.

Misfiring of the nepotistic psychology in novel environments also does not satisfactorily explain human cooperation. Based on the high degree of cooperation in foraging societies, evolutionary social scientists have often assumed that humans evolved in foraging bands comprised of kin (e.g., Maner and Kenrick, 2010). If humans had evolved in kin-based bands, then the misfiring (Barkow et al., 1992) of the nepotistic psychology in present-day environments can account for human ultrasociality. However, this is an unlikely scenario. First, there is no evidence that Paleolithic foragers lived in kin-based bands. Data from two contemporary hunter-gather societies, the Ju/Hoansi and Ache, show that only up to a quarter of the band is comprised of a person's kin (Hill et al., 2011). The other half of the band is affines, and the remaining quarter is neither kin nor affines. Second, in acephalous nomadic pastoral societies like the Turkana, multiple settlements cooperate in warfare (Mathew and Boyd, 2011). Turkana settlements disperse and regroup seasonally like hunter-gather bands. With a band-level cooperative psychology, we should expect the Turkana to cooperate on the scale of settlements. Yet, an average Turkana raid has warriors from four different settlements. Lastly, people in societies with higher market integration and larger community size are more generous in the dictator game and more willing to punish unfair offers in the ultimatum game when playing with anonymous community members (Henrich et al., 2010). The misfiring hypothesis would suggest that people living in small-scale societies that are more similar to ancestral social environments should cooperate in anonymous interactions with their peers at least as much as people in large market-based societies.

Direct Reciprocity

Direct reciprocity (Trivers, 1971) can sustain cooperation among pairs of individuals who have the opportunity to interact repeatedly. Direct reciprocity is best exemplified by the *Tit for Tat* (*TFT*) strategy, where an individual cooperates in the first round in a repeated prisoner's dilemma game, and afterward acts just as her partner acted in the previous round (Axelrod and Hamilton, 1981). Reciprocal strategies like *TFT* can outcompete defectors because its practitioners are more likely to accrue the long-run benefits of repeated cooperation than defectors who attempt to exploit them in the first round but lose out afterward. Although there are limited examples of reciprocity in other animals, some forms of human cooperation fit with reciprocity. For instance, among the Hiwi and Ache, the amount of one family's food production given to another family correlates with the amount of the second family's food production given to the first family, controlling for biological kinship, geographic proximity, and the overall amount of this resource the family gives away (Gurven, 2004). Consistent with reciprocity models, humans have 'cheater detection' systems for social exchange – specialized cognitive systems to recognize when a partner has violated a social contract (Cosmides et al., 2010).

Although *TFT* was shown to be the winning strategy against a host of other strategies (Axelrod and Hamilton, 1981), reciprocity in nature does not follow its prediction too closely. The condition for *TFT* to be an evolutionarily stable strategy against a pure defector strategy is $wb > c$, where b is the benefit the recipient gets, c is the cost for the giver, and w is the probability the pair will interact again. According to this condition if a pair will interact twice on average, they could be as cooperative as siblings. If so, there should be rampant high-stakes pairwise cooperation in humans and other animals. Yet, reciprocity has rarely been documented in other animals, although repeated interactions occur in many animal societies (Clutton-Brock, 2009). Humans display conditional cooperation, whereby we are more likely to cooperate with partners who cooperate, but the strategy we utilize pays attention to much more than what occurred in the previous interaction. For instance, people pay attention to their partner's intent, not their behavior (Falk et al., 2008). Friendship is an appropriate domain for reciprocity – it is a long-term relation between two unrelated individuals characterized by mutual aid and companionship. Yet, a study conducted in USA, Japan, and China indicate that a characteristic of friendship is that people do not track each other carefully and tolerate imbalances in help received and given (Xue and Silk, 2012).

Why is there a mismatch between reciprocity theory and real-world pairwise cooperation? One reason is that in reciprocity models which strategy prevails depends on what mix of strategies

are allowed to compete. This ambiguity prompted a recent study to examine what occurs when all possible strategies are allowed (van Veelen et al., 2012). The analysis by van Veelen et al. reveals that even when there are considerable gains to cooperation, there is only moderate cooperation in the population. The surprising pattern is caused by strategies that arise via mutation that can cooperate and thrive just as well as the common strategy, but once common, pave the way for less cooperative strategies. The population thus cycles between states that are dominated by more and less cooperative strategies. Interestingly, the authors find that if there is a small degree of assortment, repeated interactions yield much higher levels of cooperation. In humans, such assortment can arise if interactions are directed toward kin. Importantly, humans have yet another pathway for assorting. Because we acquire information through social learning, and learn what the local norms are about how to behave from our local group, interacting with cultural group members can also lead to assortment (Boyd and Richerson, 2010).

Another reason why real-world pairwise cooperation is unlike *Tit for Tat* is because *TFT* is a poor strategy when players make mistakes (Fudenberg and Maskin, 1990), fueling a quest for a variety of alternative strategies (reviewed in McElreath and Boyd, 2008; Nowak, 2006). Real-world interactions are plagued by genuine mistakes. People intend to cooperate, but may defect instead. For example, Sally agrees to pick Tom from the airport, but wrote the date incorrectly in her calendar and does not show up when Tom arrives. Such errors are called implementation errors. In another kind of error, people cooperate, but their partner may perceive it as a defection. For example, Sally arrives at the airport half an hour late because of traffic. Tom waited for 20 min and then took a taxi home. These are labeled perception errors. Resolving these errors have led to a diverse range of strategies that are not just retributive like *Tit for Tat*, but are additionally contrite – sorry for mistakes made and willing to make amends (Boyd, 1989), forgiving – occasionally cooperating with those who defect (Nowak and Sigmund, 1992), and flexible – shifting from cooperation to defection and vice versa based on remuneration under these tactics (Nowak and Sigmund, 1993). More investigation on this topic could illuminate further the emotions and behavioral strategies that underpin pairwise social relations in humans.

The Evolution of Large-Scale Cooperation

Human cooperation cannot be explained by nepotism and direct reciprocity alone. Humans cooperate with strangers, and cooperate in groups comprising millions of genetically unrelated individuals. In state societies, people regularly trade with anonymous strangers, and through taxes, contribute toward public goods like defense and capital facilities, and provide for individuals who are needy. Even without coercion from the state, people voluntarily cooperate: they donate blood, contribute to charity, assist in disaster relief, organize community events, protest unjust laws, give up their seat on a bus for an elderly person, return items to lost-and-found locations, give directions to travellers, etc.

Even politically uncentralized societies can organize cooperation at an impressively large scale. Among the Turkana, an acephalous tribal-scale pastoral society in East Africa, in addition to the clandestine stealth raids described earlier, men also mobilize for large-scale raids in which they engage in a firefight with neighboring ethnic groups (Mathew and Boyd, 2011). Such raids are a high-stakes form of cooperation – 1% of participants get killed in these raids, and 20% of all males born in the study population die in warfare. Although individuals take great risks in combat to overcome the opponent's resistance, all combatants can acquire the loot. Some gains like territory and deterrence are obtained even by noncombatants. Yet, the scale of Turkana raids is large. An average raiding party comprised of 315 warriors, who came from five different age groups, four different settlements, and three different subterritories of Turkana society. These men do not all know each other. Moreover, a warrior has on average only four close kin with him in such a raiding party.

Three mechanisms have been identified to explain the evolution of large-scale cooperation in humans: indirect reciprocity, punishment, and cultural group selection.

Indirect Reciprocity

Humans not only help those who helped them, but also help those who helped *others*. Alexander (Alexander, 1987) posited that such indirect reciprocity could explain society-wide cooperation enforced by moral systems that are based on how people treat others. Nowak and Sigmund (Nowak and Sigmund, 1998) theoretically demonstrated that indirect reciprocity can be evolutionarily stable. In this model, a pair of individuals is sampled at random from the social group. One of them is assigned to be the donor, and the other the recipient. The donor can cooperate by conferring a benefit b at cost c to the recipient, or the donor can defect. In the next round, another pair is sampled at random, and the game continues. Each act of cooperation increases a person's 'image score' while defection lowers this score. It turns out that a 'discriminator' strategy, which cooperates if its partner has a sufficiently high image score, can be evolutionarily stable against defectors if $qb > c$. Here q is the probability that the donor knows the image score of the recipient. Image-scoring was found to perform well only under a narrow set of conditions, and so has been replaced by 'standing' strategies which attend also to information on the donor's own score and to whether the recipient's past defections were justified (Panchanathan and Boyd, 2003; Leimar and Hammerstein, 2001). Nonetheless, the general consensus from the models is that cooperation can evolve by indirect reciprocity in communities where people can observe each other's behavior, or can garner honest information via gossip on who cooperates and defects in their interactions.

Key features of human cooperation are consistent with indirect reciprocity. Laboratory experiments have demonstrated that participants are motivated to help a novel partner who has helped other players. For instance, in one study (Ule et al., 2009) participants were paired at random with another participant each round. In one of the treatments the player in the donor role could help, do nothing, or harm one's partner. The majority of participants (57%) were other-regarding discriminators who helped if their partner had a reputation for helping others, and passed up on the opportunity to help if their partner did not have a history of helping others. A related observation is that humans are more cooperative when there

are cues that they are being observed, suggesting that reputation matters. In an anonymous one-shot experimental study, participants were more generous to a stranger merely when stylized eye spots were drawn on the computer screen in which they took the study (Haley and Fessler, 2005). Nonverbal cues like mutual eye-gaze and touching increased contributions in a public-goods game (Kurzban, 2001). These subtle cues that we are being watched increase cooperation beyond the laboratory too (Bateson et al., 2006). Concern for reputation fits indirect reciprocity. However, individuals who strategically cooperate only when their own reputation is at stake resemble the self-interested discriminator strategy in the study by Ule et al. where 10% of players helped their partners when their own reputation was poor rather than when their partner had a good reputation. More theoretical work is required to understand the prevalence of self-interested discriminators and why they do not undermine cooperation sustained by other-regarding discriminators.

The above models of indirect reciprocity only explain pairwise helping among members of a social group. Can indirect reciprocity sustain large-scale cooperation? To answer this, one study examined players' behavior when rounds of the indirect reciprocity game alternated with rounds in which the group played a public goods game (Milinski et al., 2002). Players were much more cooperative in this game than if they were playing consecutive rounds of the public-goods games. Thus, the reputation consequence in the pairwise game was motivating players to behave well in the *n*-person game too. Panchanathan and Boyd (2004) theoretically demonstrated that indirect reciprocity can indeed support large-scale cooperation. If individuals in a social group engage in both *n*-person and pairwise cooperation, and if those who fail to contribute in the public-goods stage are denied help in pairwise exchange, then contributing to public goods is evolutionarily stable. Attitudes toward Turkana warriors who shirk on the battlefield are consistent with indirect reciprocity's role in sustaining *n*-person cooperation (Mathew and Boyd, 2014). In vignette studies, Turkana subjects were asked either about a fictitious coward who lagged behind others on a raid, or about an unskilled warrior who put in the effort but did not perform well. Participants were more likely to say that they would not help the coward if he needed to borrow an animal from them at a time of need. Being denied such help is consequential for a Turkana herder. Herdsmen lose their stock in raids, epidemics and droughts, and without aid from their relatives and community they cannot rebuild their herds. The threat of losing such assistance must motivate warriors to not shirk on the battlefield.

Indirect reciprocity has illuminated why humans mind other's business, and how this enables cooperation, but there remain three open questions. One question is why indirect reciprocity is even needed to sustain pairwise cooperation, when direct reciprocity could suffice. Second, it is clear that cooperation should be somehow contingent on the recipient having a good standing, but what is the best system of assigning 'goodness'? For instance, if I am in good standing and I am kind to a defector, should it lower, increase, or have no effect on my standing? Should my act of kindness be viewed differently if I myself was in bad standing? To tackle this question Ohtsuki and Iwasa (2004) examined a vast range of assignment systems and found eight leading strategies. All eight of these strategies share the property that cooperating with good folks is good and defecting on good folks is bad. Moreover, in terms of all leading eight strategies it is good to defect on bad folks. Empirical studies on how humans actually adjust their impressions of others can help narrow the search further. A third issue is that indirect reciprocity models assume that information quality is sufficiently high because mechanisms like gossip allow reputational information to be broadcast. But why are people motivated to tattle tale when they personally do not stand to gain from it? And why do people not manipulate information for their own gains enough to undermine the quality of reputational information and thereby unravel cooperation? A better grasp of these issues will provide a more accurate picture of how indirect reciprocity evolved, and will get us closer to describing the structure and nuances of our moral psychology.

Punishment

Cooperation can be maintained if individuals cooperate, and at some cost to themselves, punish those who defect. Such altruistic punishment can be evolutionarily stable against defectors as long as punishment imposes a larger cost on defectors than the benefit defectors acquire by free riding (Boyd et al., 2003). An advantage of punishment is that it can maintain cooperation in much larger groups than indirect reciprocity because people do not need to know the previous behavior of everyone else in the group. For instance, indirect reciprocity alone is unlikely to maintain cooperation on Turkana raids, as raiding parties comprise a few hundred men who are drawn from different segments of society and do not know each other well. This may be why the Turkana occasionally also dispense corporal punishment to cowards and deserters in raids. A problem with punishment is that it can be undermined by second-order free riders. In indirect reciprocity, the discriminator strategy benefits from refusing to help someone in bad standing, and so are evolutionarily stable against unconditional cooperators (Panchanathan and Boyd, 2004). In contrast, because punishment is costly, unconditional cooperators or second-order free riders fare better than punishers by gaining the benefit of punishment without paying the cost (Yamagishi, 1986).

Empirically, humans are motivated to cooperate and to punish those who do not, even at a cost to themselves (Gintis et al., 2005). In a classic experiment Fehr and Gachter (2002) compared players' contribution in multiple rounds of a public goods game when players could either punish or not punish shirkers in their group. When punishment was allowed, players used it even though it cost them – 84% of players punished at least once – and consequently contribution levels increased each round. In contrast, contributions decreased each round in a typical public goods experiment without punishment because conditional cooperators who start out contributing stop doing so when they notice free riders in their group. Remarkably, experiments also reveal that the motivation to engage in costly punishment extends to uninvolved third-party observers. In the third-party punishment game, an allocator receives an endowment and can allocate any amount of it to the recipient. After the allocation, a third person – the observer – can reduce her own endowment to subtract money from the allocator. Henrich et al. conducted this experiment across 15

small-scale societies (Henrich et al., 2006). In every society, there were observers who would punish unfair allocators, even though such punishment is costly to the observer and provides the observer no personal benefit.

There is evidence that punishment supports cooperation outside of laboratory experiments too. Since their inception, state societies have utilized punishment to curb norm violators and criminals, and enforce rule of law. However, given that punishment is costly to implement, it is important to know if punishment occurs in politically uncentralized societies where there are no police and courts responsible for implementing punishment. Here the Turkana provide a useful case study. Turkana warriors report that they do indeed punish cowards and deserters in raiding parties (Mathew and Boyd, 2011). A group of age-mates find the unsuspecting violator, restrain him by holding or tying him, and beat or whip him. All the while, they reprimand him for what he did, teach him how he should have behaved, and urge him to not repeat the offense in future raids. After this, the violator may be required to kill an animal from his herd for the others to eat. The Turkana view such punishment as an intervention to correct men who have erred, rather than as an opportunity to injure a person or dispense violence (Mathew and Boyd, 2014). Age-mates and other community members discuss the matter beforehand during which differing opinions may be heard about whether punishment is warranted. Some violators are only criticized verbally and warned that if they repeat it, they will face more serious sanctions.

Punishment is generally accepted to play some role in large-scale cooperation, but there are ongoing debates about how important its role is. One point of contention is how punishment compares to rewards and other forms of positive reinforcement. Punishment may not be efficient from the group's perspective (Ohtsuki et al., 2009). Because costly punishment lowers the payoff of both the punisher and punished, in some experiments it yields lower average payoffs for the group (Dreber et al., 2008). When both the option for rewarding cooperators and punishing defectors is allowed, rewarding increased contribution levels more than punishment in the repeated public goods game (Rand et al., 2009). Other experiments contradict these findings. When the time horizon is longer than in typical laboratory experiments, punishment increased average group payoffs (Gächter et al., 2008). In the study by Ule et al. (2009) where individuals had the opportunity to either help, not help, or punish a partner, players used indirect sanctions much more often than direct punishment. However, the actions of the 10% of players who were other-regarding costly punishers were necessary to make defectors have a lower payoff than other-regarding discriminators.

Another issue is whether there is sufficient empirical evidence for costly punishment outside of laboratory experiments (Guala, 2012). Some scholars contend that in the real world punishment is typically implemented through low-cost means. For instance, the Turkana first criticize cowards and deserters, and utilize corporal sanctions when such verbal sanctions do not suffice. Moreover, a group of age-mates convene to punish a violator. Such coordinated punishment is much cheaper to implement and can evolve under a less restrictive range of conditions (Boyd et al., 2010). While a solo punisher may face physical harm and retaliation, age-mates who deliver punishment in a group escape these costs. Nonetheless, in addition to the chance of potentially losing a valuable social tie, organizing corporal punishment takes time and effort. Age mates discuss the violation, gather local age-mates, plan the punishment, find the unsuspecting violator, and discipline him. These costs, albeit lower than what is faced by a solo punisher, matter when considering the evolution of a trait. So, the question of why people are motivated to bear costs to punish free riders remains a crucial open problem.

Although some theoretical solutions to the second-order free rider problem have been proposed (e.g., Boyd et al., 2003; Henrich and Boyd, 2001), more work is needed to clarify the issue. There are virtually no empirical studies of second-order free riding in small-scale societies, which raises many questions. Do societies have cultural norms against second-order free riding? Are people motivated to sanction second-order free riders, or are we motivated to reward punishers? Is third- or fourth-order free-riding a concept in any society? Thus it remains to be seen how humans solved the critical problem of second-order free riding and evolved the capacity for punishment.

Cultural Group Selection

Indirect reciprocity and punishment have explained important aspects of human cooperation and moral motivations, but they are not complete explanations. Sanctions have the unfortunate property that they can sustain a vast range of outcomes (Boyd and Richerson, 1992). Sanctions can maintain both cooperative and noncooperative outcomes. For instance mutual enforcement can maintain the norm 'You may steal your neighbor's unguarded cows to feed your family' or 'You may not steal your neighbor's unguarded cows to feed your family'. Sanctions can also maintain norms on a wide range of scales. For example, 'Do not steal your clansmen's cattle, but the cattle of the rest are for brave men to steal' or 'Do not steal your tribesmen's cattle, but the cattle of other tribes are for brave men to steal' are both group-beneficial norms, but one benefits clans, the other benefits tribes. In the domain of property rights, cooperation occurs on the scale of clans in the former society, and on the much larger scale of tribes in the latter society.

Experimental findings too confirm what casual observations tell: human societies vary widely in the norms they enforce, and these norms support cooperation at vastly different scales. Herrmann et al. (Herrmann et al., 2008) conducted a public goods game with punishment in 16 countries, and found that participants of some countries punished individuals who contributed to the public goods, while in other countries people punished noncontributors. Antisocial punishment was more common in countries with weak rule of law and low civic cooperation. Another study comparing behavior across 15 small-scale societies (Henrich et al., 2010) showed that people in societies with higher market integration and large community size are more generous in the dictator game and more willing to punish unfair offers in the ultimatum game. This suggests that large, market-based societies have norms of fairness in transient interactions that support cooperation with anonymous strangers, whereas small-scale societies lack these norms.

A complete account of human cooperation would specify the processes that select among the many possible norms that

sanctions can sustain to yield the patterns of cooperation we observe across societies.

Cultural group selection (Boyd and Richerson, 1985) can explain why sanctions and norms support cooperation on the scale of cultural groups – symbolically marked groups of people with similar norms and beliefs. Social learning can maintain between-group variation in behavior despite substantial migration, making cultural group selection much more plausible than genetic group selection (Henrich and Boyd, 1998; Boyd and Richerson, 2010). Bell et al. (2009) tested this claim by estimating between-group variation in cultural and genetic traits among contemporary societies. The analysis shows that cultural FST values are orders of magnitude larger than genetic FST values, supporting the view that cultural group selection is far more plausible than genetic group selection. How do social learning mechanisms maintain sufficient between-group behavioral variation? Conformism – imitating the behavior of the majority – is one type of social learning mechanism that can evolve in a wide range of conditions that favor social learning (Boyd and Richerson, 1985; Henrich and Boyd, 1998). If people have conformist learning biases, then migrants into a group will adopt the behavioral variant of the new group, because they adopt the common variant in the new environment. A second way by which social learning biases can maintain between-group variation is by punishment (Richerson et al., 2003). If norm violations are punished, then new immigrants into a group will quickly learn to adopt the customs of the new social environment. As long as there is sufficient between-group variation, there are ample means by which cultural groups can compete: warfare, differential population growth, and greater success at being imitated by other groups. Consequently norms that benefit the cultural group can evolve.

There is some evidence that the scale of human cooperation is consistent with cultural group selection. Consider the following study among the Turkana (Mathew and Boyd, 2011). The Turkana are subdivided into two-dozen territorial sections each comprising 20 000–50 000 people. Participants from one territorial section – the Kwatela – were narrated one of two scenarios. In one scenario, two Kwatela warriors go to the neighboring Turkana territorial section – the Lukumong. They steal cows, and drive them back to Kwatela land. In the other scenario, two Kwatela warriors go to the neighboring tribe – the Toposa – and steal cows, which they drive back to Kwatela land. Participants, who were all Kwatela, were then asked a series of questions to elicit how they judged the warriors. Strikingly, although in both scenarios the Kwatela benefit, participants reacted extremely differently. They felt that the warriors who raided Lukumong cattle did something very wrong, deserved sanctions, and were undeserving of their help. In contrast, the warriors who raided Toposa cattle were praiseworthy and deserving of help. This means that Turkana norms governing warfare create benefits exactly at the scale of the cultural group – not at the smaller scale of territorial sections, and not at the larger scale that includes other tribes. The pattern of male mortality in Turkana suggests that the norms really matter. About half of adult male mortality is due to interethnic warfare, and only 1% is due to internal interpersonal violence. Thus, despite the ubiquity of firearms within Turkana settlements, the Turkana successfully suppress interpersonal violent conflict, and most of the conflict is between the Turkana and other tribes. If this pattern is general, there is a compelling case to be made that the ultrasocial unit in human societies is the cultural group. As cultural groups get bigger, so then will the scale at which humans cooperate.

Conclusion

For a long time, evolutionary theory did not explain human behavior as adequately as it explained the behavior of other animals. But recent models of cooperation have begun to integrate distinctive features of humans such as culture and moral sentiments into the evolutionary framework. Direct reciprocity, and the range of reciprocal strategies that deal with errors, have provided a useful framework for understanding pairwise relations in humans. Indirect reciprocity and punishment models have illuminated how humans evolved to cooperate in large groups of unrelated individuals. Finally, cultural group selection explains the scale of human cooperation, and why it is variable. There remain many unresolved questions: What reciprocal strategy underpins friendships? What is goodness? Why is gossip honest enough? Why are people motivated to punish? More theoretical work and empirical studies across a wide range of societies can help fill these gaps, and provide us a more detailed picture of how we became ultrasocial.

Human Development and Health

Linda K George, Duke University, Durham, NC, USA

Abstract

There are strong reciprocal relationships between health and human development. Developmental disabilities and delays *in utero* and in childhood are associated with compromised health at all later stages of life, including middle and old age. Conversely, physical or mental illness early in the life course stunts normal development during childhood/adolescence and is associated with disadvantaged socioeconomic status throughout adulthood.

There are strong reciprocal links between health and human development. Throughout the life course, good health provides opportunities for cognitive, emotional, and social development and poor health constrains development. Conversely, successful human development promotes health and developmental difficulties pose risks to optimal health. Although these conclusions are – and can only be – based on observational data, accumulated research findings are sufficiently consistent and strong to permit the inference that these reciprocal effects are causal.

Despite abundant evidence that health and human development operate reciprocally on each other, methodological challenges to research on this topic are substantial. Current findings typically are based on short-term longitudinal data rather than the decades of monitoring required for a fine-grained understanding of the dynamics of health and human development. In addition, research on the links between health and human development during middle-age and late life is threatened by selective mortality – i.e., by the fact that poor health and developmental failures or delays result in early death, leaving an unrepresentatively healthy and developmentally advanced population available for study.

Conceptualization and Definitions

Both 'health' and 'human development' are broad terms, covering a lot of conceptual and empirical ground. Both are defined quite broadly here. Health encompasses the broad range of indicators of physical and mental illness, as well as disability and mortality. It also is important to note that health is strongly age related. Chronic physical illnesses, disability, biological dysregulation (e.g., increased inflammation and decreased immune function), and mortality all increase with age. Mental illness has a different relationship with age, peaking in adolescence, and early adulthood.

Human development is conceptually very broad, although most research on human development can be usefully described as falling into two traditions. One tradition focuses on infancy and childhood and broadly traces the unfolding of universal characteristics and capacities as individuals traverse the early part of the life course. It is generally assumed that developmental processes and outcomes are characteristic of the species. Thus, variability is expected to be modest, although both personal experiences and broader social and cultural contexts can affect the nature and timing of developmental phenomena to a limited degree. This tradition also focuses on developmental milestones and posits that development is cumulative – i.e., that failure to attain one developmental milestone precludes the achievement of later developmental challenges.

The second tradition focuses on adulthood and aging rather than early life and was developed by scholars working from life span (the term preferred by psychologists) and life course (the term preferred by sociologists) perspectives. In this tradition, 'development' is viewed much differently. In particular, there is no expectation of universal developmental tasks. Instead, the focus is on patterns of skills, attitudes, and behaviors that emerge over the life course. These patterns both have implications for subsequent health and are, in part, a function of health. A major theme of research in this tradition is that both developmental pathways are strongly affected by social context – that social and cultural forces are the primary determinants of human behavior and that these forces will exert strong influences on the nature and timing of even those behaviors that are widely characteristic of the species. Because of dramatic differences in social systems and cultural traditions, wide individual and group variations in patterns of behavior over the course of adulthood are expected.

The Link between Health and Human Development

Scholars studying developmental processes first became interested in illness as a threat to normal development. Serious illnesses and/or disabilities can constrain an individual's ability to master developmental tasks and/or delay his or her achievement (e.g., Newacheck and Taylor, 1992; Verhoof et al., 2012). Moreover, failure to master early developmental tasks can disrupt the achievement of later ones, resulting in a snowballing pattern of developmental disadvantage. Although early research focused primarily on disruptions to highly specific developmental tasks (e.g., cognitive development, motor skills), recent research casts a wider net, including, for example, studies of how severe childhood illness can delay or disrupt the development of social skills, social relationships with family members and peers, self-esteem, and academic achievement (e.g., Verhoof et al., 2012).

Another body of research examines the relationships between health and human development from the opposite

point of view: how patterns of development influence subsequent health. From this perspective, successful accomplishment of developmental tasks (be they biologically driven or socially/culturally prescribed) is viewed as a form of resource accumulation that affects subsequent health. Failure to achieve developmental skills can affect health in both the short and long term. During childhood and adolescence, developmental failure is strongly linked to mental illness and psychological distress. But developmental failures or delays also affect health much later in the life course. A broad body of research now documents the links between early achievements – including intelligence, educational achievement, self-esteem, feelings of self-efficacy, and the social skills required for successful relationships – and health in middle and later life (e.g., Goodman et al., 2011).

Although these are distinct bodies of research, both are part of a broader and deeper intellectual transformation of how health and illness are understood by both scientists and the larger public. From the middle of the nineteenth century until the middle of the twentieth century, the *medical model* dominated our understanding of the nature and causes of illness. The medical model views illness as biological dysfunction caused by the failure of the organism's biological defenses to prevent damage or disturbance. It is a complex model, recognizing that threats to the body's integrity can be generated by either external forces (injuries, viral, and bacterial antagonists) or internal dysfunctions (congenital deficits, cellular dysregulation). But it is an incomplete model that ignores health-relevant social, psychological, and cultural factors. Since the 1950s, a multidisciplinary model, often called the *biopsychosocial model of illness*, has become the dominant theory of illness among both scientists and the general public. The major tenet of this model is that illness is a product of the complex and interacting effects of biological, psychological, social, and cultural factors. An important corollary of this model is that biological intervention alone typically cannot prevent, cure, or manage illness. Both the causes of and appropriate interventions for illness and premature mortality occur at multiple levels. Research on the reciprocal and complex links between human development and health has been an important demonstration of the utility of the biopsychosocial model of illness.

The Effects of Health on Human Development: State of the Evidence

A broad body of research documents the strong and robust effects of health at one part of the life course on subsequent developmental outcomes. The strongest evidence is from studies of the effects of childhood physical or mental illness on subsequent development during both childhood and adulthood.

Childhood physical illness is associated with several types of developmental problems and/or delays. The primary developmental outcomes examined are cognitive development and academic performance, emotional control and maturity, successful relationships with peers, and behavioral problems at home or at school (e.g., aggression, withdrawal). Numerous studies document strong and robust relationships between childhood chronic physical illness and developmental problems, especially poor cognitive/academic performance, problems developing relationships with peers, and low self-esteem (Forrest et al., 2011; Martinez et al., 2011; Pinquart, 2013; Pinquart and Shen, 2011). These problems tend to cumulate over time, leading to increasing developmental problems in adolescence (Verhoof et al., 2012). These findings apply to many specific illnesses, including cancer, cystic fibrosis, Type 1 diabetes, and epilepsy.

Childhood mental illnesses also exact a severe developmental toll (Forrest et al., 2011; Martinez et al., 2011). Indeed, children with mental disorders appear to be at greater risk of stigma, bullying, and social isolation than those with physical illnesses (Walker et al., 2008).

The developmental deficits resulting from childhood physical and mental illness continue into adulthood. Childhood physical illness is associated with lower levels of educational achievement and income during adulthood (Contoyannis and Dooley, 2010; Currie, 2009; Goodman et al., 2011). Childhood mental illness is especially damaging, exacting more severe costs on adult socioeconomic achievement than childhood physical illness (Goodman et al., 2011; Smith and Smith, 2010). This pattern may reflect the fact that childhood physical illnesses vary substantially in their effects on adult socioeconomic status (SES). Children suffering from illnesses that can be managed effectively typically attain levels of education, occupation, and income similar to those of their healthy peers (Newacheck and Taylor, 1992). In contrast, illnesses that result in frequent incapacity or threats to survival (such as cystic fibrosis) and those that involve cognitive functioning (such as epilepsy) are associated with poorer adult socioeconomic outcomes.

There is also an intergenerational component to the effects of health on development during childhood and adolescence. A broad body of research consistently reports that children who live with a parent who suffers from chronic physical illness, chronic or intermittent mental illness, and/or disability are at increased risk of developmental problems or delays (e.g., Pakenham and Cox, 2012; Sieh et al., 2013). Again, a variety of developmental problems are observed, including cognitive and learning problems, behavior problems, general social competence, and the ability to forge successful relationships with peers.

Given the strong evidence that chronic illness (of self or parent) places children and adolescents at risk of developmental problems, recent research appropriately focuses on the processes and mechanisms that account for these relationships. This is a complex issue because there are multiple pathways by which illness affects development. In broad brush, however, these pathways can be placed in two categories: characteristics of the illness and family dynamics.

For chronically ill children, characteristics of the illness, its sequellae, and the nature and efficacy of medical management all play a role in decreasing or increasing the risk of developmental problems. Some illnesses have direct effects on developmental outcomes (e.g., epilepsy can impair memory). In other cases, treatments to manage chronic illnesses create obstacles to normal development. Some medications have side effects that place the child at risk of developmental problems (e.g., inability to concentrate); other treatments (e.g.,

chemotherapy) can impair function in multiple domains. Illness severity affects development beyond the symptoms and impairments resulting from the disease. For example, the more absences from school as a result of the illness, the more severe are the developmental problems (McCubbin, 1988). Finally, the stigma associated with chronic illness can lead to rejection – or even bullying – from peers and isolation of the child (Walker et al., 2008).

Family dynamics also play a strong role in increasing or reducing the ill child's risk of developmental problems. Quality of parenting and the parents' methods of coping with a chronically ill child are especially important (Gannoni and Shute, 2010; Tartakovsky and Hamama, 2011). The entire dynamic of family life is changed by the presence of a chronically ill child. Parenting requires more time, special skills, and maintaining a balance between 'normalizing' the child's life as much as possible, while also providing high levels of supervision and medical management. Demands change over time as the illness changes and as the child ages. Providing care to a chronically ill child over long periods of time is draining and affects all areas of parents' lives (Avison et al., 1991).

Family dynamics also help explain why children often experience developmental problems when a parent is chronically ill. Two processes seem to be especially important in this regard. First, if parental illness is accompanied by high levels of marital discord, the risk of developmental problems in children is increased (Pakenham and Cox, 2012). Second, the risk of developmental problems in children is dramatically increased if the ill parent is 'emotionally unavailable' to the child (Sieh et al., 2013).

The Effects of Human Development on Health: State of the Evidence

Research on the ways that human development affects health is somewhat more difficult to identify than research on the effects of health on development. The difficulty rests, in part, on the large number of indicators that researchers view as fitting under the conceptual umbrella of human development. Physical, cognitive, emotional, and social dynamics are all viewed as legitimate developmental phenomena and each of those categories includes a large number of more specific indicators. The focus here is on developmental tasks that emerge during early life, when both normal development and its timing have been well documented.

David J.P. Barker (1997) initiated the large and increasing body of research on what is now variously known as the fetal origins hypothesis, the fetal programing hypothesis, and the thrifty phenotype hypothesis. Barker argued that human development begins in the womb and demonstrated that problems of fetal growth can affect health decades later. Although initially received with skepticism by the scientific community because of the confounding effects of environmental factors, strong support for the theory now exists. A number of fetal characteristics have been linked to health later in life, including birth weight, length of gestation, and maternal gestational diabetes. Low birth weight has received most attention and can lead to what is now known as the thrifty phenotype. In brief, when a fetus receives insufficient nutrients for optimal development, it will make metabolic adaptations to survive and develop as normally as possible. Those adaptations, however, are permanently programed into the fetus and have negative implications for later health (Victoria et al., 2008). All three fetal characteristics are associated with both childhood illnesses (Wehby et al., 2013) and increased risk of coronary heart disease, hypertension, stroke, diabetes, and some cancers in middle and later life (Barker et al., 2013; Durnwald and Landon, 2013). This body of research is arguably the strongest evidence that developmental problems cast a long arm, affecting health during middle and late life. From a more practical perspective, this research provides compelling evidence of the importance of optimal prenatal care.

Developmental trajectories after birth also affect subsequent health. Developmental problems in childhood are associated with health problems that emerge in adolescence or young adulthood. Strauss et al. (2012), for example, report that poor cognitive and social skills in childhood are risk factors for the onset of schizophrenia in adolescence and early adulthood. A wide range of developmental difficulties are associated with poor self-rated health, depressive and anxiety disorders, more school absences for short-term illnesses, and more hospital days (Blanchard et al., 2006; Boyle et al., 2011).

Developmental problems in childhood and adolescence also predict poor health in middle and later life. Deficits in cognitive and social skills during adolescence are associated with increased prevalence and earlier onset of chronic illnesses during middle and old age (Kaestner and Callison, 2011). Childhood behavior problems, especially aggression, predict the experience of sudden 'health shocks' during adulthood (Temcheff et al., 2011). An insecure attachment style, which is established by age two, is associated with adult illnesses and health risks including greater reactivity to stress, use of psychotropic and illicit drugs to control affect, cardiovascular disease, and metabolic syndrome (Maunder and Hunter, 2001).

In perhaps the most comprehensive examination to date, Nobel Prize winner James Heckman (2012) recently documented the wide ranging ways in which and ages at which developmental disabilities exact a heavy cost on health for decades.

Methodological Challenges

Several methodological issues complicate efforts to better understand the links between development and health; two are especially important. First, accurate depiction of the complex, reciprocal, and time-dependent relationships between development and health requires longitudinal data collected over most of the life course, i.e., from birth until late life. This long time span is needed because it is not until middle age that a significant proportion of the population experiences significant health problems, although the antecedents of those problems often occur decades earlier. Although the number of studies monitoring individuals over long segments of the life course has increased in the past two decades, none of them cover the optimal age range. As a result, scientists rely on cross-sectional comparisons and short-term longitudinal data sources. Until data covering the entire life course are available,

however, there is always the threat that what appear to be age changes are actually cohort differences.

Second, selective mortality poses a serious threat to our understanding of the links between development and health because both are related strongly to mortality. Selective mortality bias is a result of the fact that survivors of a given cohort are healthier and more socially and economically advantaged than cohort members who die. Consequently, as cohorts age, survivors become increasingly 'elite.' As a result of selective mortality, research that examines the links between development and health – especially studies restricted to adults – almost certainly *underestimate* the effects of development on health and, vice-versa, the effects of health on development. Selective mortality also may affect patterns observed among survivors. For example, the narrowing of SES differences in health during late life may result from earlier mortality of low SES persons rather than a 'biological leveling' at the end of life (see Zajacova and Burgard, 2013, for an extensive examination of compositional changes in aging cohorts due to selective mortality).

Future Directions

Future research on the links between health and human development is likely to focus on two major topics. First, efforts will continue to identify the specific pathways and mechanisms by which development and health affect each other. Although extant research has made important contributions to this issue, many mechanisms remain unknown. In addition, replication of findings to date is especially important because of reliance on cross-sectional and short-term longitudinal research designs. Second, future research will address the extent to which and ways in which developmental and health problems early in life can be compensated for or reversed. There will be formidable obstacles to achieving these research goals, but the benefits to human health and well-being will be worth the efforts.

Human Development, Successful: Psychological Conceptions

Werner Greve, University of Hildesheim, Hildesheim, Germany

This article is a revision of the previous edition article by W. Greve, volume 10, pp. 6970–6974, © 2001, Elsevier Ltd.

Abstract

Evaluating personal development as 'successful' presupposes the existence of normative criteria. Although psychological theories and empirical facts by themselves do not form a sufficient basis for legitimate evaluations and norms, they are nevertheless a necessary component. Accordingly, this article discusses psychological concepts that empirically describe and theoretically explain the courses and outcomes of human development. In particular, the concepts of plasticity, resilience, individual capacity to act, and social integration are examined. These concepts and the resulting psychological model of successful development will be explained by focusing on recent models of developmental regulation.

From its outset, human development is dependent on the presence of essential and beneficial conditions in the physical and social environment. Some of these conditions are fundamental and the same for all human beings (oxygen, water, food), while others are more complex and necessary to varying degrees (e.g., support of caregivers, language-education, culturally specific competencies). Human beings also differ from one another in their psychological and physical needs: congenital and acquired vulnerability and deficiencies need special support and encouragement, some of them may even require specialist intervention or preventive treatment (e.g., specialized diets in the case of inherited metabolic disturbances such as phenylketonuria) (*see* Human Development, Theories of). At any event, there needs to be a minimum degree of *fit* between the individual and his or her environment before development can actually take place. Within these bounds, however, a very wide range of human development can unfold: An individual's predispositions and qualities encounter an immeasurably vast range of diverse environmental influences (socialization, critical and nonnormative life events, historical influences, etc.). These influential factors operate throughout an individual's ontogenesis (Baltes et al., 2006). Human development never reaches completion, is multidirectional and seldom irreversible, while at the same time featuring a high degree of interindividual *variability* and intraindividual *plasticity* (Baltes, 1987, 1997; *see* Neural Plasticity). Moreover, there is now a broad consensus that human development does not take place uniformly in an irreversible sequence of different stages and phases, but is a process that individuals themselves actively influence in substantial ways (Brandtstädter, 2006; *see* Brain Maturation and Plasticity during Infancy and Adulthood).

In view of this broad range of possibilities, the question of how and under what circumstances human development can *succeed* proves to be complex in several respects. The purpose of this article is to deal with two questions. The more important, of course, is the question of what *makes* development successful (from a psychological point of view); Which are the prerequisites of an 'art of life' (Staudinger, 1999)? To answer this question, however, the term 'successful' needs to be clarified.

What Is 'Successful' Development? The Problem of Criteria

Since the work of David Hume (1739–40/1978) many have argued that while empirical sciences like psychology may, for reasons of principle, apply criteria that are value judgments, they cannot justify or legitimize the use of such criteria. According to this view, no matter how good science may be, it can only describe and explain the world, but it cannot judge it. Is the question of what makes human development 'successful' hence unanswerable from the start, at least from the viewpoint of an empirical science?

Is and Ought – Bridging a Presumed Gap

Actually, the relationship between empirical description and explanation on the one hand and value judgments and normative standards on the other is in fact more complex than that. Even if empirical facts, to begin with, do not constitute *sufficient* conditions for making evaluations, as a rule they are in many cases *necessary* ones (Brandtstädter and Schneewind, 1977). Any decision or action is predicated not only upon preferences and value judgments but also upon expectations which take account of empirical facts. For instance, the demand for a juvenile who commits crimes to be 'educated' by punishment assumes that punishment actually serves to influence his or her future actions. This is an assumption that can, and indeed must, be empirically tested. In this respect, science plays a key role in answering the question of successful development, even if the criterion for measuring 'success' has had to be determined on a prescientific basis.

Yet it is open to question whether assessments of human action and biographies really are as completely arbitrary as is suggested by a Humean perspective. Without wishing to get involved in the finer points of the philosophical debates surrounding the 'deducibility' of normative statements from descriptive ones, it can nevertheless be said that all positions purporting to offer proof of the inherent distinction between 'is' and 'ought' in fact tend to presuppose this 'gap' of principle rather than to prove its existence (Mavrodes, 1968). In search for firm foundations for value judgments as well as for empirical descriptions, the last line of defense is the practice

of simply not calling certain statements into question because the grounds for doubting them appear more dubious than the statements themselves.

So, although we can forget any prospect of finding 'the' best biography per se in the foreseeable future, indisputably negative examples can easily be identified within the variations realized. For instance, there is no doubt that a person who persistently and repeatedly violates others for no reason, leads a less 'productive' life than one who shows reasonable consideration for others' interests and needs when taking his or her actions and decisions. Likewise, one can hardly describe an old age marred by illness and loneliness, causing distress particularly to the aged person but also to his or her relatives and friends, as 'successful' without arousing the suspicion that this is an artificial, academic discussion or simply cynicism. The details of examples such as these will be controversial, and here too particular constellations will lead to changes in our assessments. Nevertheless, such examples show that in many cases value judgments ('better' – 'worse') are scarcely more doubtful than the 'brute' facts. This does not entail, however, that value judgments and normative statements can be derived from scientifically proved descriptive statements. Empirical sciences such as psychology do need additional (normative) premises if they are to progress from describing and explaining the world toward altering it. Yet, some of these premises are hardly controversial but rather undisputable.

Nature and Culture: Flexible Intersections

Human development is more than just a biological process. Since we are "unfinished animals … who complete themselves through culture" (Geertz, 1973: p. 44), human ontogenesis is in need of compensatory support by cultural and individual scaffolding and self-regulatory efforts. The 'incomplete architecture' of human development (Baltes, 1997) requires and, at the same time, allows the individual shaping of the life course (*see* Life Course: Sociological Aspects). This, of course, is the very reason why we are in need for (evaluative) criteria of what 'successful' development actually means. As a consequence of the individual's possibility to influence his or her life course, the search for universal criteria of successful development which can be applied to all people irrespective of their individual, cultural and historical circumstances, is likely to be fruitless. The actional perspective of human development entails that people's 'success' depends to no small degree on what they themselves consider to be successful. Within the development-regulating normative rules and developmental tasks of a culture, which incidentally are themselves subject to cultural development processes, the individual him- or herself organizes the ways of shaping his or her own life, looking for and construing orientations that give meaning to his or her personal development (Brandtstädter, 2006).

And yet, the individual perspective has to be complemented with a general one. Even if we are the coproducers of our development (Lerner and Busch-Rossnagel, 1981), it is constrained by the laws of nature, in particular by biological laws. Moreover, human development obviously follows a universal pathway. Since the course of human development is, like any other aspect of human beings, a result of evolutionary processes (Bjorklund and Pellegrini, 2002), its functional necessities delineate the individual's margins for self-regulation, let alone self-formation (*see* Lifespan Development: Evolutionary Perspectives). Beyond securing (or at least supporting) the individual's survival at every stage, development serves the ultimate criterion of evolution, i.e., reproduction. Beyond the preparing function of childhood and youth ('deferred adaptations'; Bjorklund and Pellegrini, 2002), the criterion of reproductive functionality (i.e., 'fitness') includes the entire life span, even up to its final stages in old age (Greve and Bjorklund, 2009; *see* Fertility Theory: Theory of Life History Evolution). The sufficient fulfillment of the respective functional necessities of every developmental stage, both with respect to survival of this particular stage and to the respective contribution to reproduction (i.e., the survival of the next generation(s)), represents another necessary condition for 'successful' development (at every stage and hence in general).

Individual development is the result of the complex interactions of both biological and cultural (social) influences. These influences, in turn, are subject to permanent changes: Beyond the biological evolution, cultural factors evolve as well (Jablonka and Lamb, 2005), and so does the mutual influence of biological and cultural influences (and their interactive interplay) (*see* Culture and the Self: Implications for Psychological Theory). Within the boundaries set by biological and cultural preconditions, the individual's actions play a pivotal role in this multilayered complexity. Hence, particularly those developmental processes which enable in the individual to act and react in his or her environment provide a basis for a further group of necessary conditions for developmental 'success.'

Taken together, these considerations point toward a solution to the question of criteria. Beyond the fulfillment of the fundamental conditions essential for life, the prerequisites for successful development are clearly those meta-competencies and meta-resources which ensure that individuals can make use of opportunities and encouragement, can compensate for deficiencies and vulnerabilities, can choose and realize their own developmental goals, and thus can actively shape their development within the framework defined by immediate and potential possibilities (Brandtstädter and Schneewind, 1977). This meta-perspective implies a multicriteria approach on the one hand, and the integration of subjective and objective criteria of 'success' on the other. In particular, the adaptivity of the developing individual, allowing and facilitating it to adapt to the biocultural niche it is confronted with, should be of particular importance.

What Makes Development Successful?

Hence, in order to answer the question of what makes development a successful one, we have to look out for those conditions that enable (or support) the individual to act and react in a way that his or her survival can be secured, capacity to reproduce (or to contribute to the reproduction of sufficiently close relatives) is maintained (or enhanced), capacity

to pursue individual goals is maintained, and capacity to compensate for losses and obstacles is preserved.

Efficacy: The Capacity to Act

If human development, though canalized by biological constraints and regulated by cultural requirements, is essentially shaped by individual action, a necessary prerequisite for successful development is the individual's capacity to act, i.e., to choose developmental goals, to make decisions, to form intentions and to put them into practice, and also to overcome resistance and to revise strategies where necessary (Brandtstädter, 2006). Acting successfully entails first the precise competencies needed to carry out a particular action in practice. Additionally, an adequate representation of these competencies and potentials in the person's self-concept is a prerequisite for an appropriate and autonomous choice to be made from among the possible developmental options.

Although difficulties of coping with developmental tasks occur throughout the life course, juvenile development serves as a good example with which to illustrate (*see* Childhood and Adolescence: Developmental Assets). Challenges such as physical changes and sexual maturation, the need of developing interpersonal skills (e.g., for relationships with the opposite sex), acquiring education, and, in particular, forming a personal and social identity are not just the storms to be weathered during adolescence; these challenges are vitally bound up with laying the groundwork for successfully solving the tasks and meeting the demands of adult life (Crockett and Crouter, 1995). In particular, social developmental tasks play a particularly prominent role during the years of youth (Petersen and Leffert, 1995). Especially at a juvenile age, the dualism involved in social integration is patently evident: at one and the same time, social integration is an aim in itself and a prerequisite for successfully fulfilling the developmental task of preparing adulthood. However, both the necessity and the opportunity to change and challenge social contexts are characteristic features of adolescence too. Since the dividing line between creatively transgressing the social rules and a deviant or pathological disregard for social limits can be a fuzzy one, these dilemmata of individuation versus integration and of autonomy versus adaptation may serve as a background for the explanation of juvenile delinquency (Coie and Dodge, 1998). Delinquent juveniles, in particular those whose deviance is 'adolescence-limited' (Moffitt, 1993), have evidently not managed to cope successfully with these tasks. Thus, personal resources of coping with discrepancies between the social demands on the one hand and the personal goals, desires, and competencies on the other gain a key function in explaining successful juvenile development. In particular, the goodness of fit between the individual and his or her social environment thus becomes an important precondition and, at the same time, a central criterion for developmental success of adolescence.

Coping: Compensate for Losses, Regulating Disappointments

Throughout our life span, but in later stages of life more than in youth and early adolescence, individuals need to compensate for losses and blocked goals: In order to regain one's capacity to solve life-problems actively (Heckhausen et al., 2010), we have to overcome disappointments to readjust our aspirations and find new goals.

Actually, human development in general can be regarded as a hierarchical, interactive sequence of micro- and macroscopic coping processes (*see* Human Development, Theories of). While current coping processes and resources are shaped by developmental conditions, coping reactions can also act as forces in creating future development. That leads on to the investigation of developmental constellations of individual and social resources that make an individual either resilient against or vulnerable to new strains as they arise. The discussion of the conditions under which people cope successfully with aging illuminates this aspect very well. Numerous studies have shown that people's ability to function and their sense of well-being are not greatly impaired as they grow old, if at all. Indicators of overall psychological status such as self-esteem, general sense of well-being, or being convinced of having control over one's own life are variables which, taken together, do not show any substantial covariance with age (e.g., Brandtstädter et al., 1993; Staudinger et al., 1995). As a consequence, the stereotype of aging being a process strongly characterized by deficiencies and loss has gradually gone out of favor as being too one-sided and incomplete, to be superseded by a more multifaceted view of 'productive' and 'successful' aging (Baltes and Baltes, 1990; *see* Retirement and Encore Adulthood: The New Later Life Course). These findings are most surprising when set against the well-documented fact that, whether in terms of cognitive development, changing sensory functions or morbidity, aging does entail a real increase in the losses and impairment people suffer (Bond et al., 1995; *see* Human Development, Theories of).

Resilience: The Integration of Regulational Layers

To this end, a plethora of processes of self-regulation performs an integrating, 'orchestrating' system (Staudinger et al., 1995); this ties in with the 'developmental system's' view on human development (proposed both from psychological and biological perspectives; e.g., Ford and Lerner, 1992; Oyama et al., 2001). Self-regulating processes can essentially be classified into two modes (Brandtstädter, 2006; Brandtstädter and Greve, 1994). In the 'assimilative' mode, goals are maintained even against resistance, and strategies are pursued tenaciously until they are achieved. Obviously development can only succeed if people are sufficiently willing and capable to pursue his or her developmental goals and to solve developmental tasks. Anyone who always gives up immediately will achieve neither essential tasks nor those of his or her choosing. Yet, sometimes a goal will be – or become – unreachable (e.g., once a woman has passed the menopause, it is just impossible to bear a child). Accordingly, in the 'accommodative' mode, when the individual is confronted with goals that are truly or are perceived to be unachievable, or with irreversible losses and deterioration, preferences and orientations are adapted in a way that avoids meaninglessness and depressive tendencies, and preserves subjective well-being, but at the same time brings new,

achievable goals into view, which revive the capacity and motivation to act.

Thus, the apparent contradiction between the growing strains and losses on the one hand and the stability of the self and well-being on the other is resolved once the personal constellations of 'resilience' are made the focus of the theoretical perspective (Baltes and Baltes, 1990; Brandtstädter, 2006; Greve and Staudinger, 2006; Leipold and Greve, 2009; Staudinger et al., 1995). In addition to the model of developmental self-regulation already mentioned (Brandtstädter, 2006), the several models of developmental regulation provide important insights that help to explain resilience in old age. For instance, the model of 'selective optimization with compensation' (Baltes and Baltes, 1990) claims that losses can be partly cushioned or alleviated by way of selective improvement (training, expertise), and compensated for as people reorient their lives or change their strategies. The life span theory of motivation (Heckhausen et al., 2010) adds that processes of 'secondary control' support the individual's strive to regain goals if formerly pursued aspirations are blocked (e.g., the goal of having a child after passing the menopause).

Unfortunately, we do not know much about the developmental conditions of the individual's ability to regulate one's development both in the assimilative and the accommodative mode (Thomsen and Greve, 2013). If the developing individual's plasticity and adaptivity are the key condition to fulfill biological, cultural, and individual goals, the conditions for the development of adaptivity are of particular importance for developmental 'success' (under all conceivable circumstances and conditions).

Conclusion: Courses and Conditions of Successful Development

In terms of cognitive functions, social integration, and self-regulation, human development features a considerable amount of plasticity (Baltes et al., 2006), which not only makes up the core prerequisite for the dynamics of resilience and the coping processes discussed here, but indeed is also a general precondition for the very possibility of life span development. Self-regulation processes are a central criterion for adaptation processes on the one hand and they substantially control them on the other.

Personal well-being and psychological health, and social integration can only be maintained and improved if the individual can be protected against unfavorable conditions by resilient resource constellations, if personal and social coping resources can help to cushion and compensate for the crises and losses that will inevitably occur, and if the individual capacity to act is largely maintained, whether by stabilizing the required conditions or by finding a new orientation toward achievable objectives. Actually, all of these aspects can be seen both as the products and the producers of successful development.

Development essentially consists in upholding and implementing the individual's capacity to adapt to the discrepancies in new situations and developmental tasks as he or she seeks (via assimilation or accommodation) to attain a solution to, or dissolution of, the discrepancies that are generating a crisis or creating a burden, if these are unavoidable in the long run. Thus, successful development implies a progressive adaptation which simultaneously maintains or indeed expands this plasticity and adaptivity. As far as we know today, this is possible – and usual – at least up to the latest years of very old age (Baltes, 1997). That leads to the somewhat tautological-sounding statement that successful development essentially means ensuring that development, i.e., progressive adaptation, will always be possible and really will occur.

The emerging perspective of adaptivity and activity as the roots of successful human development suggests essential new research perspectives focusing on sources of resiliency and vulnerability at any stage of human development. Moreover, even if the preconditions and processes are known, which provide successful development, the ways to improve the individual's capacity, to acquire, or to use them are still to be investigated. Thus, studies in applied developmental science are needed in order to discover techniques and strategies of individual and social improvement of both of these core conditions, with respect to special interventions, e.g., in the case of juvenile delinquency, as well as with respect to primary prevention of developmental crises, e.g., in the case of successful aging in very old age.

Abstract

Relational developmental systems (RDS) models frame contemporary scholarship in human development – whether in infancy, childhood, adolescence, adulthood, or late adulthood – and encourage investigations of variation both within time and across people in their trajectories of *individual↔context relations* using person-centered and change-sensitive methods. Accordingly, we contrast RDS theory-framed research with prior theoretical approaches, specifying implications of RDS theories for description, explanation, and optimization of development across the life span. We note implications for programs and policies and for promoting social justice among diverse individuals, families, and communities.

Developmental science seeks to describe, to explain, and to optimize within-individual changes and differences among individuals in these within-individual changes across the life span (Baltes et al., 1977; Lerner, 2012). Although the goals of description, explanation, and optimization existed in prior instantiations of the field – in child psychology and then in developmental psychology (Lerner, 2012) – contemporary developmental scientists approach these three objectives differently than in the past. Whether studying infancy, childhood, adolescence, or the adulthood and aging portions of the life span, contemporary scholarship in human development attempts to explain how mutually influential relations between individuals and their contexts provide the basis for individual behavior and development (i.e., bidirectional, reciprocal, synergistic, or fused relations; e.g., Tobach and Greenberg, 1984). Today, then, developmental scientists focus on systematic and successive alterations in the course of these relations and on the integration of multiple attributes of the individual (e.g., physiological, cognitive, emotional, motivational, and behavioral characteristics) and multiple levels of the ecology of human development. These levels range from the biological level through the sociocultural and historical levels, including the designed and natural environments (Bronfenbrenner and Morris, 2006; Lerner, 2002, 2006).

This focus of contemporary developmental science is framed within relational developmental systems (RDS) theoretical models (e.g., Overton, 2010b, 2012; Overton and Müller, 2013; see Lerner et al., 2013; for an example of such framing within the study of adolescent development). These models integrate the actions of the individual on the context and the actions of the context on the individual, represented as *individual↔context relations* (Brandtstädter, 1998, 2006; Lerner, 2002, 2006). The emphasis on RDS models results in the view that developmental science is a nonergodic field (Nesselroade and Molenaar, 2010). The ergotic theorem holds that data sets are marked by (1) homogeneity across individuals in a three-dimensional matrix involving persons, variables, and time; and (2) stationarity of individuals' scores on variables across time (Molenaar, 2007). Developmental scientists, however, believe that there is variation both within time and across people in their trajectories of *individual↔context relations* (i.e., *across time differences*). In other words, people differ in their paths across the life span. Accordingly, the assumptions of homogeneity and stationarity of the ergodic theorem are rejected in contemporary developmental science (Molenaar, 2007, 2010) when framed by RDS theories. As a consequence of nonergodicity, developmental scientists stress the importance of person-centered and change-sensitive methods in their descriptive and explanatory efforts.

To explain these contemporary features of theory in the study of human development we will first contrast today's RDS theory-framed field with prior approaches to theory. Accordingly, we review the evolution of ideas about developmental theory from the end of the nineteenth century and across the twentieth century. We describe the bases of the emergence of interest in RDS theories and then present an overview of key features of these conceptions. This discussion will enable us to specify the implications of RDS theories for description, explanation, and optimization of development across the life span. Our discussion of optimization enables us to formulate some concluding comments about the links between RDS-predicated programs and policies for promotion of social justice among diverse individuals, families, and communities.

Developmental Science: Past and Present

During the latter years of the nineteenth century and for much of the twentieth century, and perhaps especially in the United States and Western Europe, the study of human development became a visible subfield of psychology (see Cairns and Cairns, 2006; for a review). In this literature, and its antecedents in philosophy (see Baltes, 1983 for a review), development was envisioned to be a life-span phenomenon (e.g., Erikson, 1959; Hall, 1904, 1922). The majority of the scholarship about human development in the United States and Western Europe, however, was focused on infancy and childhood (e.g., Binet and Simon, 1905a,b; Gesell, 1929; Piaget, 1923; Preyer, 1882; Terman, 1925).

As a consequence, across this historical period, child psychology emerged as a specific subarea of psychology, spurred on by the research of scientists studying this age period, by the founding of several university centers and institutes devoted to the study of children (e.g., in Iowa, involving

scholars such as Boyd R. McCandless; Minnesota, involving scholars such as Dale B. Harris; and Yale, involving scholars such as Arnold Gesell), and by the work occurring within land-grant universities in the United States in the field of home economics that focused on children (and families) (Cairns and Cairns, 2006; Lerner and Simon, 1998). At the same time, many of these bases of child psychology also created a purportedly multidisciplinary instantiation of scholarship devoted to the study of children, that is, child *development*. In 1933, the Society for Research in Child Development (SRCD) was founded to promote such a multidisciplinary approach to the study of children (and to the application of child development research). In actuality, however, SRCD was, from its outset, dominated by scholars trained in psychology, and this is still the case today. It is not surprising, then, that whether labeled child psychology or child development, the study of the early portion of the life span was framed in very similar ways by scholars studying children (*see* Childhood and Adolescence: Developmental Assets).

At its inception, the child development (or child psychology) field was framed by Cartesian split conceptions of change across ontogeny and by reductionist accounts of the bases of human development (Overton, 2006, 2010b). The core conceptual issues of child development were the nature–nurture, the continuity–discontinuity, and the stability–instability controversies (Lerner, 2002). These debates and proposed 'solutions' involved, for instance, reducing development to being a phenomenon explained by either nature variables (genes or maturation; e.g., Hamburger, 1957) or operant or respondent stimulus-response connections (e.g., Bijou and Baer, 1961). This split, reductionist ontology about development meant that the epistemological route to learning about the basis of development was to identify the essential (nature *or* nurture) explanatory variable(s). Accordingly, the study of development was also marked by variable-centered analyses, as exemplified by the tables of contents of the editions of the *Handbook of Child Psychology* (e.g., Carmichael, 1946, 1954; Mussen, 1970, 1983) and other major compendiums (e.g., Reese and Lipsitt, 1970; Stevenson, 1963) published during this period.

However, as early as 1970, Mussen, the editor of the third edition of the *Handbook of Child Psychology*, pointed to the potential implications of the growing interest among some scientists to move away from a reductionist approach, which involved descriptions of the variables purportedly accounting for ontogenetic structure and function, and toward an approach that viewed development as involving interrelations among variables (from multiple levels of organization). Mussen (1970) said that "the major contemporary empirical and theoretical emphases in the field of developmental psychology … seem to be on *explanations* of the psychological changes that occur, the mechanisms and processes accounting for growth and development" (p. vii). By pointing to the interest in change processes, Mussen was implying that we needed something more to explain the process of development, unless we believed that nature or nurture variables explained themselves in structure or function.

That 'something more' was already emerging within the study of development – at a series of conferences held at West Virginia University in the late 1960s and early 1970s about the nature and implications of a life-span view of human development (e.g., Baltes and Schaie, 1974; Nesselroade and Reese, 1973; Schaie, 1970) (*see* Lifespan Development, Theory of). These West Virginia University conferences, and the edited books that derived from them, laid the foundation for contemporary RDS theories. First, the conferences and associated books discussed the philosophical, theoretical, and methodological problems associated with split/reductionist accounts of development. Second, they introduced ideas about the potential for plasticity (i.e., the potential for systematic change) in development across life, and they pointed to the role of potentially mutually influential relations between individuals and their normative age- and history-graded contexts, and their nonnormative experiences, in instantiating this plasticity. Finally, they underscored the fundamental necessity of studying intraindividual changes (and interindividual differences in intraindividual changes) involved in these individual↔context relations in order to describe, explain, and optimize the course of human development. These ideas would act synergistically with growing scholarship in Europe that provided theory and data fostering a 'reversal' of focus for developmental inquiry – from variable-centered to person-centered approaches to human development (e.g., Magnusson, 1999). These ideas were also synergistic with work in sociology at the time demonstrating that the course of life was shaped by historical events that one encountered at particular times and in particular places (Elder, 1974) (*see* Motivation: Life Course and Sociological Perspectives).

When taken together, these ideas pointed to the vacuity of split/reductionist models (and their attendant methods). In turn, this work underscored the importance of time and place, person↔context relations, plasticity, and the need for longitudinal (change-sensitive) methods to study intraindividual change across life, as well as the diverse life paths of these intraindividual changes. These ideas, when considered together, presented a major challenge to the then-dominant metatheoretical and theoretical ideas in the field. Indeed, the new ideas about human development formed at the West Virginia University conferences were akin to a Kuhn-like (Kuhn, 1962) paradigm shift (Lerner et al., 2013; Overton and Lerner, 2012), from the then still dominant models, methods, and ontogenetic foci associated with child development.

In addition to being primarily descriptive and normative (Mussen, 1970), with the norms usually generated by studying only a small portion of humanity (i.e., European American middle-class children in the main; Hagen et al., 1990), the extant 'paradigm' was as likely (if not more likely) to use cross-sectional research to study development than it was to employ longitudinal methods. The use of cross-sectional designs (and data analysis methods, e.g., R-technique analyses; e.g., see Cattell, 1966, and for more current versions of these ideas see Nesselroade and Molenaar, 2010) was predicated on the assumption of the applicability of the ergodic theorem (e.g., Molenaar, 2007), that is, as noted, that one could assume interindividual homogeneity and across-time stationarity of the modeled parameters (but not necessarily of an individual's observed values). In addition, because of the presumption that the descriptions being generated from

research were explained by the split, reductionist conception framing the research, studies during this period were also largely atheoretical in character (Bronfenbrenner, 1963; McCandless, 1967; Mussen, 1970). As such, selections of methods (e.g., the use of experimental designs, as in Reese and Lipsitt, 1970) or data analytic techniques (e.g., analysis of variance, factor analyses) were given priority over theory-based questions in the framing of research.

The work being generated through the advent of the life-span (Baltes et al., 2006) and life-course (Elder and Shanahan, 2006) perspectives, and the emergence of what are now termed RDS theoretical models (Overton, 2011; Overton and Müller, 2013) were linked – at least initially through the West Virginia University conferences – to these perspectives. For example, Riegel's (1976a,b) dialectic model, Lerner's (1978; Lerner and Kauffman, 1985) developmental contextual model, Magnusson's (1999) individual-context model, and Overton's (1984, 2003) organismic contextual model coalesced to shift the 'paradigm.' These strands merged in the 1970s, 1980s, and 1990s to create a focus on person↔context relations and *person↔context models* (Cairns and Cairns, 2006; Lerner, 2002, 2006). As we have noted, these models involved the belief that time and place matter in regard to shaping the course of life (Bronfenbrenner, 2005; Elder, 1998, 2013) and emphasized that developmental science needed to study both the person and the diversity of people in order to understand human development.

In short, the outcome of these theoretical ideas is that the study of development is the study of nonergodic phenomena. Accordingly, across the last decades of the twentieth century there were innovations in methods of designing research about, and analyzing data from, the study of within-person trajectories and differences between people in these trajectories. Developmental psychology per se, however, had neither sufficient conceptual tools nor methodological means to gather and interrelate variables from the multiple levels of analysis needed to describe the *individual↔context relations* involved in human development, to explain these relations, or to test these explanations through optimization efforts. As such, ideas from several disciplines were drawn on to create integrative, nonreductionist, and systems models of human development and, as well, methods from numerous fields (e.g., computer science, economics, neuroscience, molecular biology, sociology, and statistics, as well as psychology) were used to study development. By the beginning of the twenty-first century, true developmental science had been created (Magnusson and Cairns, 1996).

In sum, then, in much of the twentieth century the study of human development was embedded in a Cartesian world view: It gave great credence to a split conception of the world and thus perpetuated interest in the nature–nurture issue (Overton, 1973, 2010b). Similar core conceptual issues within the field included the continuity–discontinuity issue and the stability–instability issue, both framed within this split conception (see Lerner, 2002; Overton, 2006, 2010b, 2012; for reviews). These (false) conceptual commitments led researchers to readily accept genetic reductionism and embrace several theories (or approaches) that claimed to show how genes provided the fundamental material bases of human behavior and development (e.g., behavior genetics, sociobiology, or evolutionary psychology). The apparent truth of these assumptions was maintained, in part, by avoiding consideration of the ecology or context of human development (e.g., see Greenberg, 2011; Gottlieb, 1998; Overton, 2012; for critiques).

Moreover, scientists working within this context focused on what might be called the 'generic human being' (Emmerich, 1968) and on the earliest years of life, progressing in the best cases to the years surrounding puberty (Brim and Kagan, 1980). Today, however, in the middle of the second decade of the twenty-first century, developmental science conceptualizes the entire span of human life as involving change. It also rejects prior conceptions of a nature–nurture divide and its associated problems, embracing instead the importance of the *individual↔context relations* noted earlier.

RDS Theories

RDS theoretical models are, today, at the cutting edge of theory and research within developmental science (e.g., see the two volumes of the *Handbook of Life-Span Development*; Lamb and Freund, 2010; Overton, 2010a). Such theory focuses on the processes that govern mutually influential relations between individuals and their contexts. Brandtstädter (1998) terms these relations 'developmental regulations' and notes that where developmental regulations involve *mutually beneficial individual↔context relations*, they constitute *adaptive* developmental regulations.

With RDS models, all levels of organization within the ecology of human life are involved in mutually influential relationships across the breadth of the entire life course (Bronfenbrenner and Morris, 2006; Riegel, 1975, 1976a,b). The broadest level of the context is history (temporality) and, as a consequence of all levels of person and context being embedded in history, there is always a potential for systematic change – for plasticity (Lerner, 1984) – in *individual↔context relations*. Indeed, given that variation exists across time within contexts and, as well, across contexts within time, differences in time and place constitute vital contributors to plasticity across the life span – even into the 10th and 11th decades of life (Baltes et al., 2006; Elder, 1980; Elder and Shanahan, 2006; Elder et al., 1993). As a consequence, human life is variegated and changing. The processes of human development are neither uniform nor permanent across individuals, settings, or history. As such, the impact of temporality in human development involves the individual life span as well as generational and historical time (Elder, 1998; Elder et al., 1993) (*see* Motivation: Life Course and Sociological Perspectives; Ecology of Aging).

In addition, the array of individual and contextual variables involved in these potentially plastic *individual↔context relations* is virtually infinite. Estimates are that the odds of two genetically identical genotypes arising in the human population is about one in 6.3 billion, and each of these potential human genotypes may be coupled across life with an even larger number of life course trajectories of social experiences (Hirsch, 2004). Thus, the number of human phenotypes that can exist is fundamentally infinite, and the diversity of development becomes a prime, substantive focus

for developmental science. To emphasize the point, it is useful to note that recent studies have produced ample empirical information about the relational developmental character of genetic processes (e.g., see Charney, 2012; for a review).

Current genetic research (1) underscores the embeddedness of genetic processes within processes from other levels of organization of the fused, relational developmental system; (2) documents the idea that *gene↔context relations* are part of the plasticity of within-individual change; and (3) provides a conception of the genome that contradicts the concept of genes found in behavioral genetics, sociobiology, and evolutionary psychology. For instance, Charney (2012) points to how the contemporary scientific study of genetics is signaling not only a nonsplit approach to developmental science but, as well, is tolling a death knell for these genetic reductionist approaches. He says that,

> Rather than being an unchanging template, DNA appears subject to a good deal of environmentally induced change. Instead of identical DNA in all the cells of the body, somatic mosaicism appears to be the normal human condition. And DNA can no longer be considered the sole agent of inheritance. We now know that the epigenome, which regulates gene expressivity, can be inherited via the germline. These developments are particularly significant for behavior genetics for at least three reasons: First, epigenetic regulation, DNA variability, and somatic mosaicism appear to be particularly prevalent in the human brain and probably are involved in much of human behavior; second, they have important implications for the validity of heritability and gene association studies, the methodologies that largely define the discipline of behavior genetics; and third, they appear to play a critical role in development during the perinatal period and, in particular, in enabling phenotypic plasticity in offspring (p. 331).

This evidence, along with that supplied by others (e.g., Ho, 2010; Ho and Saunders, 1984; Greenberg, 2011; Gissis and Jablonka, 2011; Hood et al., 2010; Jablonka and Lamb, 2005; Molenaar, 2010), creates the basis for a true Kuhnian paradigmatic revolution in the study of development (Kuhn, 1962). The findings presented by these scholars constitute anomalies (in effect, falsifications) of the 'old' genetic reductionist paradigm. These anomalies result in a crisis for the reductionist paradigm and, critically, a basis for science (and for working scientists) to turn toward an available, alternative paradigm. This new paradigm is RDS theories and, consistent with Kuhn's (1962) discussion of scientific revolutions, the very findings that are anomalies in (falsifications of) genetic reductionist models (and methods) are integrated within the now-dominant paradigm (Overton and Lerner, 2012).

Simply, to the extent that developmental scientists have successfully validated their theoretical models of the intra-individual change trajectories linked to specific instantiations of *individual↔context relations*, their work should be able to be applied to enhance the likelihood that diverse individuals will be on better (i.e., healthier, more positive) trajectories. Although developmental science will only move asymptotically toward this knowledge base, current emphases in developmental science (Fisher et al., 2012) stress that scholarship should be directed to identifying the answers to questions about how to use integrated explanatory/optimization work to create a more socially just world for diversity of individuals in our global community. This contemporary interest in the connection between basic and applied developmental science that serves social justice may portend a continued focus on an applied developmental science that contributes to social justice in future decades (Lerner, 2012).

Conclusions about RDS Theories

From the perspective of RDS models, to adequately describe and explain human development across the life span, scientists need to focus on the substantive significance of diversity. They must attend to the diversity of *individual↔context relations* that exist within people across time (this diversity makes implausible the ergodic theorem postulation of stationarity across the life span) and they must attend the variation across people in these varying trajectories of within-individual change (this diversity makes implausible the ergodic theorem postulation of homogeneity across people) (Molenaar, 2007). In addition, an RDS theoretical approach to understanding the life course has implications as well for optimization, the third goal of developmental science.

Optimization within RDS Theoretical Approaches to Developmental Science

The focus on diversity in regard to describing and explaining developmental change that is emphasized within RDS theories also involves the expectation that, as a consequence of health-supportive alignments between people and settings, positive changes can be promoted across all instances of variation in *individual↔context relations*. With this stance, diversity becomes the necessary subject of inquiry in developmental science. That is, to understand the bases of and, in turn, to promote *individual↔context relations* that may be characterized as healthy, positive, adaptive, or resilient – which are relations reflecting the maintenance or enhancement of links that are mutually beneficial to individuals and context – scholars must ask a complex, multipart question (Lerner et al., 2012, 2013). Specifically, researchers must ascertain,

- *what fundamental attributes of individuals* (e.g., what features of biology and physiology, cognition, motivation, emotion, ability, physiology, or temperament); among individuals of
- *what status attributes* (e.g., people at what portions of the life span, and of what sex, race, ethnic, religious, geographic location, etc. characteristics); in relation to
- *what characteristics of the context* (e.g., under what conditions of the family, the neighborhood, social policy, the economy, or history); are likely to be associated with
- *what facets of adaptive functioning* (e.g., maintenance of health and of active, positive contributions to family, community, and civil society)?

Moreover, proponents of RDS models believe that the relative plasticity of the *individual↔context relations* creates a synthesis between the explanatory and optimization goals of

developmental science (Baltes et al., 1977; Lerner, 2002). To test explanations of developmental change, scholars need to institute or evaluate programs that are aimed at altering the bidirectional relations expected to produce changes in behavior and development. These actions must necessarily be embedded in the ecologically valid settings of human development in order to have generalizability to the lived experiences of individuals and, therefore, must constitute intervention (applied) research and, at the same time, research testing basic explanatory processes of human development. As such, in contemporary developmental science, the commonly regarded split between basic and applied research is also regarded as a flawed holdover from earlier eras (Fisher et al., 2012; Lerner and Overton, 2008). In short, the application of developmental science (optimization) is a coequal partner with description and explanation within contemporary developmental science.

The emerging approach to developmental science also brings to the fore a concern for promoting social justice (Fisher et al., 2012; Lerner and Overton, 2008). Arguably, the most arduous test of the integrated explanatory/optimization scholarship conducted by developmental scientists involves efforts to bring to scale changes in the developmental system for diverse individuals. If our explanatory models can fully account for the system of *individual↔context relations* that alter the course of development for all individuals, then we should be able to promote more positive development among all individuals. Developmental scientists should be able to specify *what* characteristics, of *what* individuals, should be integrated with *what* features of the ecology of human development, at *what* points across ontogeny, to produce *what* instances of (more optimal) changes in behavior and development (*see* Ecology of Aging). Longitudinal projects, such as the Berlin Aging Study (Baltes et al., 2006) or the 4-H Study of Positive Youth Development (J. Lerner et al., 2013), involve such specifications: in those studies, findings illustrate the importance of research framed by RDS models in explaining the course of development and generating rich ideas for optimization strategies.

Accordingly, rather than optimize their theories to promote success of a 'generic' or 'ideal' person, within-individual developmental systems work should be able to be applied to enhance the likelihood that diverse individuals will be on better (i.e., healthier, more positive) trajectories. Answering the above noted 'what' questions is essential if scholars are to use their integrated explanatory/optimization work to enhance policy and programming, and thereby, create a more socially just world for a diversity of individuals in our global community (Fisher et al., 2012). RDS theories suggest that, through the plasticity of individual↔context relations, means may be found to move all people toward living on a more 'level playing field.' Evidence from RDS-predicated research may be used, then, in policy and program innovations aimed at leveling the playing fields of life for diverse individuals, families, and communities.

Conclusions

The future of RDS theories in developmental science, as a superordinate frame for scholars in psychology, sociology, economics, biology, medicine, education, and other fields interested in describing, explaining, and optimizing the course of human life, seems assured. One bit of evidence in support of this prediction is that the forthcoming, seventh edition of the *Handbook of Child Psychology* will be published in 2015 by John Wiley and Sons with the expanded title of the *Handbook of Child Psychology and Developmental Science* (Lerner, 2015). Across the four volumes of this publication, volume editors (Volume 1, on theory and methodology; Volume 2, on processes of cognitive development; Volume 3, on processes of socioemotional development; and Volume 4, on ecological processes) emphasize the use of RDS perspectives and, as well, point to the implications of this theoretical frame for both understanding and enhancing *individual↔context relations*.

In the future, developmental science will emphasize rigorous, theory-predicated research about the mutually influential relations among individual and ecological processes, about the embodiment of human development within the rich and complex ecology of human life. Methodological innovations about how best to study the relational developmental system in manners maximally sensitive to time, place, and human diversity will therefore continue to be areas of active scholarship. Here we expect greater attention will be paid to tools for multimethod research, to creative ways to partition the x-axis in manners reflecting the diversity of developmental processes, to systems science methods (Urban et al., 2011), and to the triangulation between micro and macro analyses of within-individual change (Werner, 1948, 1957).

In turn, we believe that the application of developmental science will continue to be a core and integrated concern of developmental scientists. The theoretical orientations and interests of new cohorts of developmental scientists, the requirements imposed by funders for producing scholarship that matters in the real world, and the needs for evidence-based means to address the challenges of the twenty-first century will coalesce to make Kurt Lewin's (1952: p. 169) statement "There is nothing so practical as a good theory," an oft-proven empirical reality. Indeed, we believe that the scientific and societal value on which the developmental science of the future will be judged will be whether its theoretical and methodological tools are productive at promoting positive human development across the life span for the diverse people of the world. Therefore, developmental science as a means for promoting social justice may be the most significant lens through which the future contributions of developmental science will be viewed.

Human Ecology

Dudley L Poston, Jr., Texas A&M University, College Station, TX, USA

Abstract

The author distinguishes human ecology from ecology and focuses on sociological human ecology as elaborated by Amos Hawley. The author outlines the ecological orientation and introduces several examples of applications of human ecological theory to empirical investigations of the demographic processes. Human ecology is concerned with the organizational aspects of human populations that arise from their sustenance-producing activities. The author also outlines the theoretical and conceptual bases of the four referential constructs of human ecology, namely, organization, population, technology, and environment, reviews some of the empirical and theoretical literature spanning more than five decades, and shows in particular that demographic models benefit from using the ecological perspective.

Introduction

Otis Dudley Duncan once wrote about the difficulties defining human ecology and the perspective of human ecology as follows: "Even a provisional statement of [its] concerns will doubtless encounter strong objections from one or another group of scientists and thinkers who regard their studies of man as exemplifying the ecological viewpoint" (1959: p. 679). In this article, the author first presents various definitions and approaches of human ecology to illustrate its variant aspects and features. In the major part of this article, the author focuses on what he refers to as 'sociological human ecology,' discusses its principal dimensions and characteristics, and outlines its conceptual rubrics.

What Is Human Ecology?

The word ecology is from the Greek *oikos* (οἶκος) meaning 'household,' or 'place to live'; ecology may be defined as the "study of the interrelationships of organisms with their environment and each other" (Smith and Pimm, 2013). One of the earliest statements was that of the Greek philosopher Theophrastus, an associate of Aristotle, who focused on the "interrelationships between organisms and between organisms and their nonliving environment" (Smith and Pimm, 2013). Ernest Haeckel (1868 [1876]) was the first to actually use the term 'ecology' in his study of plants, and the term made its way into the English language with the translation of his book in 1876. The term 'human ecology' was first used by Robert Park and Ernest Burgess in their *Introduction to the Science of Sociology* (1924). For the first several decades after the term was first introduced, there was little agreement among sociologists about its meaning and focus (Alihan, 1938; Gettys, 1940; Firey, 1945). Even to this day, there are an assortment of approaches and orientations.

Freese (2001) has noted that the approaches to human ecology mainly differ according to the preferred vantage points of the scholars. He has discussed three orienting perspectives: (1) the biological perspective began with Haeckel who, following Darwin, defined ecology within the context of evolution and the "adaptations of organisms to the biotic and abiotic features of their environments" (Freese, 2001: p. 6974); since humans are living organisms, human ecology then emerged, although biologists per se have taken only a passing interest in the ecology of humans; (2) the metaphorical approach began with theories of community succession that biologists used in studying natural communities; Freese (2001) has written that some sociologists have used 'nature' as a metaphor to understand social organization; and (3) the ideological approach started in the 1960s with the genesis of the modern environmental movement worldwide; here the "biological and metaphorical interpretations of ecology are freely interwoven and supplemented with value judgments" (Freese, 2001: p. 6974) more or less in line with ecological science.

The major treatment of human ecology in sociology is Amos Hawley's book, *Human Ecology: A Theory of Community Structure* (1950), which to this day is the definitive exposition of the field. Hawley's book sets out the subject matter of human ecology and its approach. According to Hawley, human ecology deals with "how growing, multiplying beings maintain themselves in a constantly changing but ever restricted environment" (1950: p. 66). For human populations, this requires examining the ways in which individuals act collectively to achieve more effective use of their habitat (Poston and Frisbie, 2005).

Despite this clear and unambiguous sociological statement, some sociologists have ascribed to human ecology perspectives that are inconsistent with Hawley's thinking and that of McKenzie (1924, 1934, 1968), his predecessor and teacher. Here are three examples.

First, the sociobiologist Pierre van den Berghe has noted that "sociologists who claim to be ecologists … have reduced this specialty to a pedestrian kind of social geography (where) they largely plot social characteristics of people on maps" (1990: p. 174). Second, sociologists John Logan and Harvey Molotch have written that "in human ecology, spatial relations are the analytical basis for understanding urban systems" (1987: p. 4). And, third, the social theorist Manuel Castells has discussed the parallels between Marxian and ecological thinking and has observed that the results obtained by ecology have no more value for establishing

a theory of space than a mass of sociocultural correlations (1979: pp. 122–123). Not only is Castells' comment misguided, it does not capture the important materialistic and organizational similarities and differences between Marxist and ecological theory (see Hawley, 1984).

The above representations of human ecology as focusing on spatial relations are due in part to the unfortunate statement of McKenzie (1924) when he defined human ecology as the "study of the spatial and temporal relations of human beings as effected by the selective, distributive and accommodative forces of the environment." Hawley noted that although this simple, lucid statement inspired a great amount of empirical investigation, it caused human ecology to be regarded as nothing more than the descriptive study of spatial distributions, an outcome that McKenzie later noted was a misplacement of emphasis. Attention to spatial patterns, McKenzie recorded in his notes, should be subordinate and incidental to the analysis of sustenance relations (see Hawley's remarks in McKenzie (1968: pp. xiii–xiv); Poston and Frisbie, 1998, 2005).

There are other examples of the misuse or misunderstanding by social scientists of human ecology. Some refer to human ecology as studies using spatial rather than individual units of analysis (Robinson, 1950), as analyses of the physical features of geographic and built-up areas (Zorbaugh, 1929; Suttles, 1972), or as the factor analyses of the characteristics of aggregate units, i.e., factorial ecology (Berry and Rees, 1969).

These illustrations all exemplify Duncan's observation that "the term ecology is sometimes applied rather casually – even irresponsibly. [Frequently] studies adopting the label bear only a tenuous relationship to any systematic, scientific conception of the field" (Duncan, 1959: p. 680).

Sociological Human Ecology

Human ecology is a field of study grounded in the four referential constructs of population, technology, organization, and environment. The unit of analysis is the human population, circumscribed more or less in a territorial fashion. Its major assumptions are that populations have unit character and integrity, and that properties and attributes of these populations are more than the summation of their component parts (Poston and Frisbie, 1998, 2005).

Human ecology is concerned with the organizational aspects of human populations that arise from their sustenance-producing activities. These activities are necessary for the collective existence of the populations and must be adapted to the changing conditions confronting them. Included are an ever-changing and mediating environment, their technological repertoires, and the size, composition, and distribution of the populations themselves (Duncan, 1959; Frisbie and Poston, 1975, 1978a, 1978b; Poston, 1980, 1981; Poston and Frisbie, 1998, 2005).

Human ecologists address questions such as, what are the structural arrangements that characterize a population's sustenance-related endeavors? Under what conditions does one form of sustenance structure appear rather than another? What are the consequences for populations of varying configurations of sustenance-producing activities?

The answers lie in the fact that populations survive by virtue of collective organization. Human ecology is concerned with the determinants and consequences of sustenance organization, a consideration, by the way, that addresses the interplay between human ecology and demography. Thus, it is not surprising that much of the empirical literature of human ecology focuses on demographic applications, a point that will be made more evident below.

Human ecology offers demography an aggregate perspective for the analysis of the demographic processes. A fundamental tenet of human ecology is that a population redistributes itself through the vital processes and migration to achieve a balance or equilibrium between its size and life chances (Hawley, 1968: p. 331; also see Davis (1963)). Duncan (1959: p. 708) also emphasized the important ecological connections between organization and population size. Hawley (1950) noted that human populations will adjust their size through any of the demographic processes to maintain an equilibrium with their sustenance organization. Stated in another way, "demographic structure contains the possibilities and sets the limits of organized group life" (Hawley, 1950: p. 78; see also Poston, 1983; Poston and Frisbie, 1998, 2005).

Human Ecology's Four Rubrics

The author noted above that human ecology is grounded in the four referential constructs of population, technology, organization, and environment and now discusses each of these rubrics separately.

Organization

It is not an overstatement that organization is the fundamental element of the subject matter of human ecology. This is so because it is a social organization that mediates the balance among population size, growth, and distribution and the natural environment upon which it depends (Micklin, 1973). Human ecology is concerned with the organizational aspects of human populations arising from their sustenance-producing activities (Frisbie and Poston, 1978b: p. 14). In fact, the two broad goals of human ecology are to establish (1) the causes and (2) the consequences of particular characteristics of sustenance organization in human populations (Gibbs and Martin, 1959: p. 33).

There is major agreement regarding the centrality of organization within human ecology (Duncan, 1959; Hawley, 1950; Gibbs and Martin, 1959; Micklin, 1973; Poston et al., 1984; Namboodiri, 1988, 1994; Poston and Frisbie, 1998, 2005). However, despite its central position in human ecology and in the ecological theory of migration, the idea of sustenance organization was for decades in a primitive state of development both conceptually and empirically. Indeed, most of the research on sustenance organization that ecologists conducted in the 1950s and 1960s treated the concept as if it referred solely to the division of labor. This occurred even though there was little in the ecological literature to warrant such a limitation.

The notion of organization in human ecology is multifaceted. A major dimension of sustenance organization involves what Hawley referred to as the "arrangement of differentiated parts suited to the performance of a given function or set of functions" (1950: p. 178). This is sustenance differentiation, i.e., the extent to which the population is differentiated in its sustenance activity.

Sustenance differentiation consists of two elements: (1) the number of activities and (2) the degree of uniformity in the distribution of the population across the activities. A high degree of sustenance differentiation obtains when there are a relatively large number of activities characterizing the population and when the population members are evenly distributed across these activities (Gibbs and Poston, 1975).

Scholars since Durkheim (1893 [1960]) have included this dimension as a major component of the division of labor. There are many measures of sustenance differentiation, six of which have been elaborated by Gibbs and Poston (1975).

Another dimension of sustenance organization is functional interdependence; it can be combined with sustenance differentiation to form the other side of the division of labor (Gibbs and Poston, 1975). The degree of functional interdependence in a population depends on (1) the number of exchange linkages, (2) the variety of products involved, and (3) the volume of exchange flows (Eberstein and Frisbie, 1982). Empirical indicators of functional interdependence are often based on commodity-flow data.

A third dimension of sustenance organization is the volume of sustenance produced by the population, that is, the degree of productivity of the particular configuration of sustenance activities.

A fourth dimension of sustenance organization is the degree of efficiency of the sustenance organization. Given the level of sustenance produced, how efficiently does this occur? How much effort is required to produce the sustenance, whatever its volume?

A final structural characteristic or dimension of sustenance organization is the degree to which population members are engaged in sustenance-related pursuits (Poston and Johnson, 1971; Martin and Poston, 1972, 1976). What patterns of utilization of population members characterize the organization of one ecological unit versus another, especially with regard to ascribed statuses? How fully realized are the potential contributions of population members? To what extent do inequalities exist in the population by ascribed statuses? The degree to which populations differentiate by ascribed statuses in allocating sustenance roles to their members is an important dimension of sustenance organization, especially if the analyst is interested in sustenance productivity and other input-related functions (Poston and Frisbie, 1998, 2005).

Population

It goes without saying that of the four ecological concepts, population is the most advanced in terms of conceptual and operational detail. This is easily understood since an entire specialization, demography, is devoted to the study of population characteristics and dynamics. However, with few exceptions (Poston and White, 1978; Frisbie and Poston, 1978b; Namboodiri, 1994; Poston and Bouvier, 2010), ecologists seldom examine dimensions of the population as influences on population redistribution. Yet it is well known from demographic research that such population variables as age, race, and sex composition have predictable effects on demographic outcomes, especially on migration. Given the very advanced nature of the population rubric, additional attention is not necessary. The details about this rubric may be viewed in any introductory demography text (Poston and Bouvier, 2010).

Technology

Of the four basic ecological categories, technology is the most critical for the adaptation of human populations. Lenski has noted that technology is the 'prime mover' in the process of social change and adaptation for at least three reasons: (1) it sets the boundaries for feasible social and economic options; (2) technological change appears to be more easily accepted by the population than change in organization or ideology; (3) it is "easier to compare the effects of alternative tools or techniques than it is to compare the effects of alternative systems of social organization or alternative ideologies" (Lenski, 1970: p. 102; Poston and Frisbie, 1998, 2005).

The concept of technology is prominent in ecological and other macrolevel sociological theories. And there is a consensus with respect to its definitions. Three dimensions figure prominently in the definitions: material features (tools, capital equipment, and machines), information (knowledge, techniques, and scientific discovery), and energy. These are the same three ecosystem 'commodity' flows that Duncan (1964) identified as basic to the survival of populations.

Scholars have given only minimal attention to applying the technology component of the ecological complex to the study of populations below the societal level. As a consequence, there are few guidelines to suggest points of departure in specifying particular technological applications as foci.

One approximation toward conceptualization is the belief that one of the long-recognized technological keys to the establishment and growth of population aggregates is the presence and development of adequate transportation facilities. More than 100 years ago, Cooley (1894 [1930]: pp. 75–83) observed that population and wealth will tend to come together wherever there is a break or an interruption in routes of transportation. The development of transportation facilities partially determines industrial concentration and influences the expansion of local populations (Hawley, 1981). Since the availability of transportation is a major determinant of the ease of access of a population to its environment, a population's ability to compete with other populations, and the efficiency of sustenance extraction, an important dimension of technology, should involve mobility facilitating technology (Poston and Frisbie, 1998, 2005).

Two empirical indicators of this dimension of technology are the presence of an interstate highway crossing a county (or state or province) and the intersection in the area of two or more interstate highways. While these measures may be 'obvious,' the obviousness of their influence does not imply either triviality or simplicity. In fact, there is a large literature dating back to the 1960s that testifies both to the importance

and complexity of the impact of interstate arteries on subarea population change in general and change due to migration in particular (Dickinson, 1964; Wheat, 1969; Gauthier, 1970; Fuguitt and Beale, 1976; Briggs, 1980; Lichter and Fuguitt, 1980).

A second kind of technological application deals with the acquisition of sustenance. At a minimum, ecologists need to develop indicators of this dimension that reflect technological inputs affecting both primary and transformative sustenance activities. Many demographers, for instance, have noted that areas for which agricultural enterprise constitutes a major economic base are apt to experience demographic, especially migration, losses as agricultural production becomes increasingly mechanized and productive and capital intensive. However, previous research has found that (1) where production is highly land intensive or (2) where large volume and capital intensive production of food and fiber predominate, positive demographic changes predominate (Frisbie and Poston, 1978b).

Regarding the transformative component of sustenance acquisition, a useful indicator of the employment of available technology is new capital expenditures. These will index at least the hardware and capital-equipment dimension of technology in the manufacturing sector, i.e., the capital goods, equipment, and machines that figure prominently in the definitions of technology cited above. Of course, it is clear that capital may be substituted for labor, so that high levels of new capital expended might well mean a leveling off, if not an outright reduction in, local employment opportunities (Poston and Frisbie, 1998, 2005).

Environment

In human ecological terms, the environment is defined as "whatever is external to and potentially or actually influential on a phenomenon under investigation" (Hawley, 1968: p. 330). The concept of environment occupies a central position in the general theoretical framework of human ecology mainly because the environment is the ultimate source of sustenance for a population (Hawley, 1968: p. 330). However, little empirical research in sociological human ecology takes the environment directly into account, perhaps because of its breadth. That is, by definition, the environment "has no fixed content and must be defined anew for each different object of investigation" (Hawley, 1968: p. 330). In fact, some hold that the environment is the "least well conceptualized of the variables constituting the ecological complex" (Berry and Kasarda, 1977: p. 14).

However, close scrutiny of the ecological treatment of the environment reveals an implicit specificity not apparent in the above general definition. The environment comprises not everything external to the phenomenon of interest, but only those externalities that, by virtue of the limits they set on the acquisition of sustenance, affect the life chances of an organized population with a given technological repertoire. As Leo Schnore noted over 50 years ago, "the environment is viewed as a set of limiting conditions, which may be narrow or broad, depending upon the technological devices and modes of organization that prevail in a given population" (Schnore, 1958: p. 628; see also Michelson, 1970). Therefore, the human ecologist should narrow the arena of inquiry to those factors that, in light of existing technology, serve as limiting (or enabling) resources for the adaptation and growth of populations.

The author notes here that it is not useful to consider social and economic activities (or aberrations) of local populations to be part of their environment. Certain of these activities, for example, employment in given industries, are best viewed as aspects of ecological organization. Others, such as crime and deviance, rates of mortality and morbidity, unemployment, education, and income levels, are best conceived as indicators of different aspects of life chances that emerge from a population's organized efforts to adapt to the environment. In a real sense, the latter variables tend to indicate the degree of success or failure of the adaptive process. In short, they may reveal a disequilibrium between population and life chances. As such, they should be useful in helping to account for variation in a demographic process such as migration and thus should be included in models designed to explain migration. But they should not be conceptualized as aspects of the environment.

Despite the difficulties that arise in attempts to give conceptual and operational substance to the concept, it is clear that the ecological environment has two broad and distinct dimensions: the physical and the social. Hawley has written that the environment "includes not only the physical and biotic elements of an occupied area but also the influences that emanate from other organized populations in the same and in other areas. In certain circumstances the latter acquire a more critical importance than the former" (1981: p. 9).

Specifically, Hawley distinguished two dimensions, the biophysical and the ecumenic. The "former includes physiographic features, climate, soil characteristics, plant and animal life, mineral and other materials," and so forth. In contrast, the ecumenic refers to the "ecosystems or cultures possessed by peoples in adjacent areas and beyond" (Hawley, 1986: p. 14).

Poston et al. (2009) have undertaken an analysis among the states of the United States of the effects of physical climate on net migration. They gathered data on 11 different climate variables and used factor analysis to reduce them to the three dimensions of temperature, humidity, and wind. They showed that the temperature and humidity dimensions were significantly associated with migration, even after controlling for the effects on migration of factors dealing with ecological organization, the social environment, and population (see also Poston and Bouvier, 2010).

Conclusion

In this article, the author attempted to distinguish human ecology from ecology, and then to focus on sociological human ecology as mainly elaborated by Hawley (1950, 1998). The author outlined the ecological orientation, and also introduced several examples of applications of human ecological theory to empirical investigations of the demographic processes.

It was necessary to first set out the general orientation of sociological human ecology, mainly because of the fact that even today, despite the immense number of publications providing evidence to the contrary, the field is still

misunderstood by many sociologists and social scientists to be either a descriptive exercise or any kind of aggregate analysis. The author showed that some still hold that human ecology represents spatial or aggregate investigations of human phenomena. This representation minimizes considerably the rich sociological context of human ecology and indicates misunderstanding, perhaps even ignorance, of its orientation and subject matter.

The broad theoretical purview of human ecology may be distinguished from a narrower focus of ecological theory on demography. Human ecology is concerned with the organizational aspects of human populations that arise from their sustenance-producing activities. For the purposes of this selection, the author noted that human ecology offers demography a specific aggregate perspective for the analysis of the demographic processes (Poston and Bouvier, 2010).

The last part of this section outlined and articulated the theoretical and conceptual bases of the four referential constructs of human ecology, namely, organization, population, technology, and environment. The author reviewed some of the empirical and theoretical literature spanning more than five decades and showed in particular demographic models of migration benefit from use of the ecological perspective. Accentuated were the explicitly sociological features of the ecological perspective in a demonstration of its fruitful employment in demographic investigations. The strictly spatial studies that so many have thought to be ecological not only are not ecological, but also are usually not sociological. Moreover, they are theoretically lacking and are of little utility for demographic investigations (Poston and Frisbie, 1998, 2005).

This article is a revision of the previous edition article by J.L. Mountain, volume 10, pp. 6984–6991, © 2001, Elsevier Ltd.

Abstract

Traditionally, our knowledge of human evolution has come from the fossil and material culture records, and has been studied by paleontologists, anthropologists, archaeologists, anatomists, and – to some extent – linguists. In the past 25 years genetics has made substantial contributions to this field. While much of this has been driven by advances in molecular biology techniques (i.e., the methods used to obtain genetic data), the principles underlying how genetic data can be used to make inferences about our evolutionary past come from the field of population genetics. In this article we discuss how population genetics has been used to address two sets of questions regarding human evolution: (1) when and where did human populations originate (demographic history) and (2) to what extent and in what ways have humans adapted to changes in our ecology by natural selection (adaptation history).

Introduction to Population Genetics

Genetic information is carried by the sequence of bases in deoxyribonucleic acid (DNA). One of the most important features of the DNA molecule is its ability to be replicated, and so be passed on from a cell to its daughter cells, and from one generation to the next, mostly unchanged. Much of human DNA (referred to as the human genome) appears not to have a direct function, and is sometimes referred to as junk DNA. In the past it was generally thought that the only functionally important parts of our genome were genes – regions of DNA that provide information on how to make specific proteins – and regions near those genes that control their expression. However, in recent years other genomic regions have been shown to be important, such as those coding for functionally active ribonucleic acid (RNA) molecules.

During the replication process, some changes can occur in the DNA sequence; any such change is termed a mutation. Mutations can occur in reproductive and nonreproductive cells (i.e., germ and somatic cells, respectively). However, only mutations occurring in germ cells are heritable and therefore a substrate for evolutionary processes. Mutations give rise to new genetic variants, called alleles (Kimura, 1971), and the overall constellation of alleles in an individual is known as its genotype. It should be noted that mutations are relatively rare – even on the evolutionary timescale – so most of the DNA sequences in our genome are identical between individuals, and indeed between humans and other primates. However, the human genome is very large (around 3 billion base pairs) so while comparatively rare, sites in the genome (loci) that are variable between individuals are still numerous. In addition to mutation, a process called recombination can shuffle the distribution of alleles along DNA sequences into new combinations (see later).

The field of population genetics is chiefly concerned with describing and understanding the distribution and fate of genetic variation. Ultimately, an allele only has two fates, loss (from the population) or fixation (i.e., loss of variation at that locus). However, in the intervening time between mutation and loss or fixation a locus will be variable or polymorphic. The distribution and fate of genetic variation in a population is shaped by three processes: mutation (including recombination), genetic drift, and natural selection. Mutation, as explained above, gives rise to variation, natural selection favors (and so increases/decreases in frequency) particular alleles, and genetic drift is the random sampling of alleles from one generation to the next through reproduction, and leads to random changes in allele frequencies through time.

When a new mutation occurs in the protein-coding region of a gene, or in other functionally important parts of the genome, it may change the biological characteristics (phenotype) of an individual. While phenotypes are only partly determined by genotype, they can affect the overall fitness of individuals, and hence lead to differential survival and reproduction. This process is known as natural selection, and it can act on phenotypes related to early development and survival to reproductive age (viability), on success in attracting a mate (sexual selection), on the consequent ability to fertilize (gamete selection), or on the number of progeny produced (fecundity). The sum of these various selection stages constitutes the fitness of a phenotype, which is partly dependent on environmental variables. The selection coefficient is the relative fitness of a genotype or genotypes in relation to others.

A new mutation might not affect the underlying phenotype. Such mutations give rise to alleles that are neither advantageous nor disadvantageous, and are said to be neutral. The fate of neutral mutations is determined by random genetic drift – the chance passing on alleles to future generations. Genetic drift reduces genetic diversity through time since it ultimately leads to the loss or fixation of alleles, but its effect depends strongly on the effective size of the population considered.

The effective population size (N_e) is the size of a randomly mating population that would show the same degree of genetic drift as the actual population (Wright, 1931). The relationship between effective and census population sizes (N_e and N, respectively) varies depending on certain properties of the population considered (Rice, 2004). For example, if we assume

that individuals mate randomly and generations are not overlapping, then when N changes through time it can be shown that N_e is the harmonic mean of N over a given period of time. In such conditions, N_e is disproportionately affected by small values of the fluctuating population size, and N_e will be smaller than the average value of N across generations. However, these assumptions do not always hold (Rice, 2004).

The effect of genetic drift can be illustrated by looking at the chance an allele has of being fixed in a population. For autosomes (chromosomes other than the sex chromosomes: X or Y) the probability of fixation of a new allele equals its relative frequency in the population and is therefore $1/(2N_e)$; $2N_e$ because every individual carries two copies of each autosome. For the Y chromosome (one copy, only carried by males) or the mitochondrial DNA (mtDNA; only transmitted by females) this probability is approximately $1/(0.5N_e)$, and for the X chromosome (2 copies in females, 1 copy in males) this probability becomes approximately $1/(1.5N_e)$. This highlights that the larger the population the less is the effect of drift since the smaller the chance a new allele has of being fixed in this population.

An appreciation of the importance of genetic drift emerged from a major branch of population genetics called Neutral Theory (Kimura, 1971). Prior to this it was thought that natural selection was the most important force shaping the fates of alleles, and so evolution. Neutral Theory itself arose out of the realization that there was far more genetic variation in natural populations (including humans) than could be maintained by natural selection alone. It postulates that most mutations give rise to alleles that are either disadvantageous – so lost rapidly from the population – or are selectively neutral, or sufficiently nearly neutral that drift rather than selection is the main force governing their fate. Neutral Theory does admit the possibility of selectively advantageous alleles arising by mutation, but assumes that such events are sufficiently rare that they contribute little to overall patterns of genetic variation (Kimura, 1968).

One interesting prediction of Neutral Theory relates to the rate of change of DNA sequences through time. If selection plays a major role in the determination of survival of new mutations, then a constant mutation rate should not lead to a constant rate of evolution (substitution rate, or the rate of fixation of new alleles). Instead the substitution rate would be expected to vary episodically through time, as selection intensity acting on different traits varies. Alternatively, if the Neutral Theory holds then it is expected that the substitution rate is set by the underlying mutation rate and the proportion of new alleles that are selectively disadvantageous (the selective constraint). Given that the mutation rate (μ) and selective constraint for any given gene is approximately constant through time, this predicts that the rate of genetic change is also constant over all evolutionary lineages. This is known as the molecular clock hypothesis (Kimura, 1968; Zuckerkandl and Pauling, 1965) and it permits the estimation of lineage/species divergence times using genetic data.

Neutral Theory has had a profound effect on population genetics; so much so that while there are undoubtedly examples where natural selection has shaped the fate of alleles, neutrality is now widely accepted as the null hypothesis – the default assumed status of alleles at polymorphic loci.

Given that patterns of genetic variation in populations are shaped by mutation, drift (itself shaped by demographic history) and natural selection, it stands to reason that those patterns of variation in populations contain information about mutation, demographic history, and natural selection. However, extracting that information to make inferences about our evolutionary past is not trivial, primarily because any particular pattern of variation in one or a set of populations can be the result of a very wide range of different evolutionary scenarios (equifinality).

Population Genetics Inferences: Demographic History and Natural Selection

One of the advantages of the neutral model of evolution is that it makes predictions about the relationship between patterns of genetic variation, the mutation rate, and demographic parameters, such as the effective population size (Kimura, 1968; Zuckerkandl and Pauling, 1965). These predictions include: (1) the expected level of diversity within a species at equilibrium is a function of the mutation rate and the effective population size; (2) as two species diverge, they accumulate differences at the same rate (i.e., substitution rate) at which neutral mutations arise; and (3) the expected allele frequencies in a sample of DNA sequences is a function of the effective population size and of the sample size.

These predictions can then be compared to empirical data (Zuckerkandl and Pauling, 1965). From there, any significant deviations from neutral expectations would suggest the locus or loci under study did not evolve neutrally but instead were subjected to other forces, including natural selection. In other words, the study of natural selection is mainly based upon tests of significant deviation from the null hypothesis of neutral evolution, rather than any direct measurements of selection. However, an important complicating factor is that real populations typically have complicated demographic histories that cannot be collapsed to a single population size parameter, and some demographic histories can lead to patterns in genetic variation that mimic those formed by natural selection (e.g., Currat et al., 2006).

A wide-range of methods have been developed to detect genomic signature of natural selection. These methods differ primarily in the nature of the genetic data they consider and the evolutionary time frame they are sensitive to. Allele frequencies and other measures of genetic variation can be used to estimate the extent and nature of demographic changes, and population structuring, or departures from neutrality.

The extent of Hardy–Weinberg disequilibrium can be used as a crude test of neutral evolution. The Hardy–Weinberg theorem assumes an idealized population with an infinite number of randomly mating individuals, no selection, no mutation, and no migration, and predicts that for a single locus with two alleles, the three genotypes *AA*, *Aa*, and *aa* follow the proportions p^2, $2pq$, and q^2, where p and q are the initial relative frequencies of the two alleles *A* and *a*, respectively. Different types of natural selection will alter these proportions in distinct ways (Nielsen, 2005). However, any deviation from Hardy–Weinberg equilibrium can be due to various factors, such as population structure, and should thus be treated with caution

as evidence for selection. Importantly, natural selection affects only those selected alleles, while demographic factors and genetic drift act on the whole genome.

Classical methods for detecting selection are based on the distribution of allele frequencies in single nucleotide polymorphisms (SNPs), also called the allele- or site-frequency spectrum (SFS)-based methods. The allele-frequency spectrum can be 'unfolded' or 'folded' depending on whether the derived and the ancestral (i.e., fixed in other Apes) allele can be distinguished or not, respectively. This basically involves identifying the number of allele-frequency classes observed, and counting the number of loci falling in each frequency class. When considering the SFS negative selection tends to increase the proportion of low-frequency variants compared to neutral expectations (Nielsen, 2005).

Alternatively, a new mutation arising in a population may be advantageous, in which case it will increase in frequency in the population by *positive selection*. Much interest has focused on positive selection due to its association with adaptation and the evolution of new forms and functions. Over a prolonged period, positive selection increases the fixation rate of beneficial function-altering alleles. It can be detected by comparison of changes between species. The first test of selection based on detecting regions where patterns of variation depart from those expected under neutrality is the Hudson–Kreitman–Aguade (HKA) test (Hudson et al., 1987). It compares levels of diversity in different genes or genomic regions, calibrated by between-species divergence rates for the same regions, to test whether these levels are significantly increased or reduced in the region of interest, compared to theoretical expectation or empirical data for presumed neutral parts of the genome (Nielsen, 2005).

Balancing selection is a case of positive selection where the new variant is advantageous in combination of other alleles. Balancing selection thereby increases the proportion of intermediate-frequency variants with respect to neutral expectations, whereas positive selection increases the proportion of high-frequency variants.

A *selective sweep* is an example of positive selection where the new favored variant reaches a high frequency in the population, resulting in an overall decrease of the genetic variation at the selected locus, as well as in the genomic region surrounding it. A selective sweep tends to increase the proportion of low-frequency variants in respect to neutral expectations.

A widely-used type of a selection test based on the SFS is Tajima's *D* test (see Tajima, 1989). In cases of a selective sweep or purifying selection, this test detects an excess of low-frequency variants (indicated by negative values of *the* Tajima's *D* statistic) compared to what is expected under neutrality, or to empirical data for presumed neutral parts of the genome. Alternatively, in cases of balancing selection this test detects an excess of alleles of intermediate frequency (indicated by positive values of *D*). Other extensions of this type of tests are based on similar principles (e.g., Fay and Wu, 2000).

Selection can also differ between populations. This may happen due to adaptations to local environment, in which cases the level of population differentiation may increase for loci under different selection in different populations. The Lewontin–Krakauer (1973) test was one of the first neutrality tests to use the level of genetic differentiation between populations. This test rejects neutral evolution when differentiation between populations at specific locus is larger than that expected under a neutral model, or is outside the empirical range observed in presumed neutral regions of the genome. Other tests have been developed under the same principle (reviewed in Nielsen (2005)). Notably, Akey et al. (2002) used genome-wide data to look at the variation in F_{ST} (a traditional measure of allele-frequency difference between populations) in humans. Various statistical methods can use genome-wide scans to detect selective sweeps without prior hypotheses on candidate genes or regions under selection (Nielsen, 2005).

Another feature of selected genomic regions is an increase in the level of linkage disequilibrium (LD). When a new allele arises it is physically linked to alleles at other loci nearby on the same chromosome. This generates a nonrandom association of alleles known as LD, and initially, any new allele will be in complete LD with other nearby alleles. These combinations of alleles in a region of a chromosome are sometimes referred to as haplotypes. Over time, recombination breaks down the association between alleles at nearby loci, and the allele of interest will become associated with an increasing number of different haplotypes. LD also decreases with increasing genetic distance from the selected site as recombination shuffles allele combinations in proportion to distance away from it on the chromosome. Thus, the number and lengths of haplotypes associated with an allele of interest can act as a proxy for the age of that allele. If an allele has been positively selected then it will rise to high-frequency quicker than expected under genetic drift alone. It therefore follows that high-frequency alleles that are still in high LD with other nearby alleles (i.e., are recent in origin) are good candidates for selection. These principles have been used to develop a number of statistics for detecting recent and strong natural selection. For example, the extended haplotype test identifies tracts of homozygosity (identity in randomly drawn pairs of sequences) associated with a core haplotype using the 'extended haplotype homozygosity' (EHH) statistic (e.g., Voight et al., 2006). A haplotype containing an allele that has been positively selected is expected to display high EHH values and high frequencies. In contrast, haplotypes that reach high frequencies due to genetic drift are likely to have taken longer to reach those high frequencies and are therefore likely to have been subjected to more recombination and mutation events, and would consequently show lower values of EHH.

A fundamental problem with some methods of detecting genomic signatures of natural selection is the bias generated when genetic data are obtained not through direct sequencing, but by genotyping SNPs that have been discovered in other samples. This is called *ascertainment bias*. Patterns observed in the data, such as allele frequencies, population differentiation, and LD, all depend on the procedure used to discover these SNPs. For example, ascertained SNPs will almost invariably be biased toward more common variants, thus skewing statistics based in the SFS. Additionally, many SNPs were identified in only a subset of populations, particularly Europeans. When the SNP-discovery protocol is known, statistical methods can be used to correct for ascertainment biases to some extent (e.g., Voight et al., 2006).

More importantly, most methods for detecting selection are challenged by the confounding effects of demographic history

(e.g., Przeworski, 2002; Currat et al., 2006). For example, Tajima's *D* test can reject a neutral model of evolution if the population has undergone an expansion or was strongly structured (e.g., Przeworski, 2002) since an expansion can lead to an increase in the proportion of low-frequency variants, mirroring the effect of a selective sweep, and the population structure can lead to an increase in the proportion of intermediate-frequency variants, mirroring balancing selection. Allele surfing, a process whereby a rare allele is driven to high frequencies at the wave front of an expanding population, can also mirror a selective sweep (e.g., Currat et al., 2006). Alternatively, a preferential loss of low-frequency variants is expected to occur during a population bottleneck, thereby leading to an excess of intermediate-frequency variants, mirroring balancing selection.

In consequence, failure to reject a neutral model of evolution for a locus might be the result of a particular demographic history. Methods to account for the confounding effects of demography usually involve comparisons of distributions of genomic patterns of diversity at a locus of interest – such as selection–detection statistics – to those derived from the rest of the genome (which is presumed to be mostly neutral), or generation of distributions of statistics under specific demographic scenarios by simulation, and detection of outliers (e.g., Xue et al., 2009). These methods involve modeling specific demographic histories by computer simulation. Alternatively, a recently developed method for genome-wide data sets accounts for shared population history and gene flow by generating an empirical pattern of covariance in allele frequencies between populations from a set of markers (Coop et al., 2010). This is then used as a null model for identifying loci involved in local adaptation by looking at unusual correlations between allele frequencies and ecological variables (Coop et al., 2010).

An alternative approach to detecting selection makes use of advances in ancient DNA analysis to directly assess the rate of allele-frequency change through time (Wilde et al., 2014; Sverrisdottir et al., 2014). While this approach currently requires the assumption of population continuity between temporally distinct DNA samples (Sverrisdottir et al., 2014), it does have some key advantages over other methods. First, it is a direct method to test for selection, unlike others based only on contemporary DNA samples. Secondly, given sufficient data it has the potential to detect episodic changes in selection intensity through time. Thirdly, unlike some approaches it is not dependent on estimates of mutation or recombination rates (Wilde et al., 2014).

The Origins of Modern Humans: The Genetic Record

Population genetics is grounded in mathematics and probability theory (e.g., Kimura, 1968). The field has however become fundamentally data driven since the discovery of the ABO blood group system. Cavalli-Sforza and Edwards (1964) estimated genetic distances between five populations based on five different blood groups and inferred a tree in which Europeans were separated from an Afro-Asian lineage. A larger study analyzing 35 proteins linked Europeans and Asians to the exclusion of Africans, estimating a Europeans/Asians split ~55 000 years ago and an older divergence from Africans ~120 000 years ago (Nei and Roychoudry, 1974).

As genetic data increased, multivariate methods, such as principal component analysis (PCA), started to be used to summarize patterns of variation for multiple genetic markers (including HLA and blood group protein markers) over space (Cavalli-Sforza et al., 1994). Spatial gradients of allele frequencies were often interpreted as corresponding to hypothesized linguistic or cultural expansions. It has however been shown that spatial patterns of genetic variation can arise even when no major demographic events have occurred (Novembre and Stephens, 2008) but simply because similarity between locations tends to decay with geographic distance, as predicted under an isolation by distance (IBD) model.

One of the earliest influential genetic studies of human origins examined mtDNA variation from worldwide population sample of 147 individuals (Cann et al., 1987). The inferred maximum parsimony tree indicated that the deepest branches were in Africa and a molecular clock estimate placed the deepest split, that is, the time to the most recent common ancestor, at just less than 200 000 years ago. Despite the caveats of this study, notably the 'African sample' was actually a sample of African Americans, and the maximum parsimony analysis used mid-point rooting, instead of the more reliable out-group rooting, these results were corroborated some years later by a more robust study (Ingman et al., 2000). Since then, estimates of the time to the most recent common ancestor (TMRCA) for mtDNA and the Y chromosome have been highly influential in studies of human evolution. Estimates for mtDNA TMRCA currently range around 140–240 kya (e.g., Behar et al., 2012) while, until recently, estimates for the Y chromosome TMRCA ranged between 60 and 140 kya (e.g., Wei et al., 2013).

These TMRCA estimates for mtDNA and the Y chromosome differ considerably and might initially seem contradictory. However, large differences are expected for two major reasons. First, the variance in expected TMRCAs is large compared to its mean, as predicted by coalescent theory (Kingman, 1982). Second, the mode of inheritance of mtDNA and the Y chromosome (maternally and paternally inherited, respectively) mean they may have different effective population sizes.

Coalescent theory is a retrospective mathematical model of gene genealogies for a sample of DNA sequences under a defined population history (Kingman, 1982). Demographic processes shape the pattern in which those lineages (i.e., branches on a genealogical tree) connect to one another. We say those lineages converge or 'coalesce' when this process is looked at backward through time. Gene coalescence can be thought of as drift run backwards through the genealogical tree. However, while drift and coalescence are conceptually related, simulating coalescence backward through time is considerably more computationally efficient than simulating drift forward through time, because it only considers the sample, not the whole population. Coalescent theory shows that the expected TMRCA is $2N_e$ in generations, and the final time interval, when the remaining two lineages coalesce (i.e., join) into the MRCA, represents more than half of the variance in the TMRCA. This is because coalescences take longer when there are fewer lineages and those times will tend to strongly affect the shape of the genealogy.

These high-expected variances in TMRCAs have been highlighted by the recent discovery of a Y chromosome lineage branching at the basal portion of the Y chromosome genealogical tree (Mendez et al., 2013). This Y chromosome lineage was identified in individuals of West Africa origin and recent West African descent, and was labeled A00 (Mendez et al., 2013). The updated Y chromosome genealogical tree provided a TMRCA estimate of 338 kya (95% confidence interval (237–581) kya) (Mendez et al., 2013). This estimate does not only predate current mtDNA TMRCA but also the earliest anatomically modern human fossils. This demonstrates that interpretation of TMRCA date estimates for a single non-recombining region of the genome should be treated with caution – they do not necessarily represent the founding dates of a population or species. Furthermore, because of the ubiquity of past migration and the stochastic process inherent to gene genealogies, it is difficult to infer the geographic origin of a genealogical lineage from its current distribution (Beaumont et al., 2010).

Regardless of the TMRCA estimates, studies of mtDNA variation (Cann et al., 1987; Ingman et al., 2000) and of nonrecombining regions of the Y chromosome variation (e.g., Ke et al., 2001) in modern populations are consistent with, and have been interpreted as strongly supporting a recent African origin of our species. This relies on the observation that Africa is the source of the deepest lineages and harbors the greatest diversity. The genetic diversity of both systems is characteristic of a rapidly expanding population or one that was subject to positive selection, that is, long terminal branches and excess of low-frequency polymorphisms. A similar signal was also identified in various autosomal regions (e.g., Voight et al., 2005). A demographic process where modern humans expanded out of Africa between 50 000 and 100 000 years ago and replaced other archaic humans has been shown to better explain the general pattern of genetic diversity observed (e.g., Fagundes et al., 2007).

Although classification systems vary, archaic humans refer to any *Homo*-related fossil remain that is not anatomically modern humans (*Homo sapiens sapiens*). Traditionally, and prior to the development of molecular genetics techniques, information on the morphology and behavior of our ancestors and the related species at different times came from fossil and archaeological evidence. One of the most widely known archaic human groups is Neanderthal (*Homo neanderthalensis*). It represents a morphologically distinct group, with robust morphology, large brains, and prominent brow ridges. These fossils date to between 250 000 and 39 000 years ago (Higham et al., 2014) and have been found in Europe and western and central Asia. In contrast, the earliest widely accepted fully modern human skull is Omo I, from Ethiopia, and dates to 195 000 years ago (McDougall et al., 2005).

Recently, the genomes of two archaic human forms, Neanderthals (Green et al., 2010) and Denisovans (Reich et al., 2010), have been partially sequenced, thereby providing some estimates of the relationships of ancient and modern humans. This was performed by first focusing on biallelic SNPs where two present-day humans carry different alleles and the archaic human genome carried the derived allele, that is, not matching chimpanzee (Green et al., 2010; Reich et al., 2010). Then a measure called *D(H1,H2, A, chimpanzee)* was computed to assess the difference in proportion of matching when the derived allele in the archaic human (*A*) genome matched the modern human genome *H1* more often than the modern human genome *H2*. *D* is positive if the archaic genome matches *H1* more often and negative if it matches *H2* more often. This measure led to an estimate of the proportion of Neanderthal ancestry in genomes as 1–4% (Green et al., 2010) and 4–6% of Denisovan ancestry in Melanesian genomes (Reich et al., 2010). It thus appears that Neanderthals and Denisovans did contribute some ancestry to non-African modern humans.

Adaptations and Detection of Positive Selection

We now inhabit radically different ecological (e.g., hot/cold and tundra/forest), cultural (e.g., variety of food resources and of their uses and social and mating systems) and demographic (high population densities and rates of gene flow) environments worldwide. Environmental changes have triggered human adaptation, a process that involves physiological, biochemical, and behavioral adjustments. Genetic adaptations are additional responses of humans to changing environment.

Genome-wide scans have the potential to generate lists of putatively selected genes that can be further studied from a functional perspective. The most striking examples of signals of selection include those identified in genomic regions involved in human pigmentation (e.g., Wilde et al., 2014) and for genetic polymorphisms conferring some resistance to malaria (Kwiatkowski, 2005) and other infectious diseases (e.g., Fumagalli et al., 2012). Both emphasize that the various environments we have evolved in, either in the form of climate factors (e.g., Hancock et al., 2010) – such as ultraviolet exposure – or of pathogens (e.g., Fumagalli et al., 2012) have driven components of our evolution. In this respect, evidence for correlations between patterns of genetic variation and environmental variables (e.g., Hancock et al., 2010), such as temperature, precipitation, solar radiation, latitude, or elevation, have been identified. However, identifying the precise selective pressure and assessing the functional advantage of candidate genetic variants remains a challenge.

EDAR

This challenge is well exemplified by genes involved in hair follicle development, which have shown higher levels of population differentiation than expected under neutrality. In particular, the ectodysplasin-A receptor gene (*EDAR*; MIM 604095), located on chromosome 2q12.3, plays a central role in generation of the primary hair follicle pattern. In humans a derived allele in the *EDAR* gene, called *EDAR370A*, results in a valine-to-alanine substitution at position 370 of the protein sequence. This allele is associated with thicker hair in East Asian populations (Kamberov et al., 2013) has shown a strong signal of positive selection using tests based on the SFS (e.g., Kelley et al., 2006), haplotype structure (Voight et al., 2006) and population differentiation (e.g., Xue et al., 2009). Using haplotype analysis, the *EDAR370A* allele has been dated to between 1133 and 73 996 years ago (Bryk et al., 2008), but the reasons for strong selection are not yet known.

The only selection hypothesis explicitly formulated so far is that this allele may have been beneficial under Asian climate conditions some 25 000 to 10 000 years ago; a time when the climate was significantly colder and dryer than present in eastern and northern Asia. This hypothesis proposes that the *EDAR370A* allele contributed to increase lubrication and humidification of exposed surfaces (face and scalp) during the dryer and colder Ice Age in East Asia (Chang et al., 2009).

This has however not been supported by a recent study reporting an *EDAR370A* mouse model (Kamberov et al., 2013). In this study *EDAR370A* mice showed (1) increased hair thickness; (2) a higher mammary branch density and smaller mammary fat pad area; and (3) an increase in eccrine sweat gland density (Kamberov et al., 2013). This study also showed that *EDAR370A* was associated with (4) tooth variation (including single and double shoveling of the upper incisors); and (5) a higher active eccrine sweat gland density in Han Chinese (Kamberov et al., 2013). A spatially explicit forward in time simulation model, integrating the origins and spread of farming populations and fitting to observed modern allele frequencies, suggested that *EDAR370A* arose in East Asia around 30 000 years ago (95% credible interval 13 175–39 575 years ago) with selection a coefficient among the highest estimated for the human genome (0.122 with a 95% credible interval 0.030–0.186).

This nonetheless does not explicitly tell us which of *EDAR370A* pleiotropic effect/s was/were the actual target of natural selection. For example, as *EDAR* affects the development of sweat glands and hair morphology, it may be hypothesized that *EDAR370A* alters thermoregulation, and possibly mate preference. Alternatively, mammary gland branching and/or fat pad size may have been the adaptive phenotype, either because of associated benefits on lactation (not-yet assessed) or because of increased mate preferences (Dixson et al., 2011). Identifying the selective pressure on *EDAR370A* and the target phenotype of this selection are made difficult by the various developmental pathways in which *EDAR* is involved.

LCT

Pathways involved in nutrient intake, digestion, and metabolism are essential to energy production and growth, and consequently to development and survival. Since the range expansions out of Africa, our species has undergone several dietary transitions, including a shift from a diet based on animal hunting and a broad range of food gathering to a diet based on farming domesticated plants and animals (Luca et al., 2010). This Neolithic transition had profound effects on our diet, particularly dietary breadth and carbohydrate content. The Neolithic transition dates back to about 11 000 years ago in its core regions and marks the transition from foraging (i.e., hunter-gathering) to food-producing (i.e., farming) societies. It is associated with changes that include an increasingly sedentary lifestyle; the development of alternative economies that focus on animal and/or plant domesticates; and technical innovations that include polished stone tools and pottery.

The dietary breadth of farming populations is known to be narrower than that of hunter-gatherers (Luca et al., 2010). Patterns of genetic variation in the gene coding for lactase (*LCT*) provide what is probably the strongest evidence of genetic adaptation to dietary specialization (Holden and Mace, 1997; Gerbault et al., 2011). Lactase is the enzyme that digests the milk sugar lactose. It is expressed in young mammals but its expression usually decreases after the weaning period is over; a trait known as lactase nonpersistence. However, in certain human populations many adults continue to express lactase throughout adulthood, a trait termed lactase persistence.

Large differences in the frequency of lactase persistence in different populations have been known for some time (Holden and Mace, 1997). More recently, at least four independent alleles associated with lactase persistence have been identified indicating convergent evolution in different geographic locations (Enattah et al., 2007; Gerbault et al., 2011). In Europe and southern and central Asia, a single allele (–13 910*T*) predominates, whereas in the Middle East and Africa three additional alleles (13 915*G*, 13 907*G*, and 14 010*C*) are commonly found in lactase-persistent individuals. Furthermore, the correlation between the distribution of lactase persistence and the distribution of pastoralism/dairying (Holden and Mace, 1997) provide strong support for a gene-culture coevolutionary process.

Selection coefficients on the -13 910*T* allele have been estimated to be between 1.4 and 19% using extended haplotype homozygosity (Bersaglieri et al., 2004), between 5.2 and 15.9% using spatially explicit simulation modeling (Itan et al., 2009), and around 2.4% using ancient DNA (Sverrisdottir et al., 2014), among the highest of the human genome over the past 30 000 years. Furthermore, the age estimates for the –13 910*T* allele are relatively recent: 2188–20 650 years ago using extended haplotype variation (Bersaglieri et al., 2004), 7475–10 250 years ago using closely linked microsatellite variation (Mulcare, 2006) and 6256–8683 years ago using simulation modeling (Itan et al., 2009). These age estimates bracket dates for the domestication of milkable animals and dairying.

Our knowledge of the evolution of lactase persistence in Europe has benefitted considerably from archaeological data, notably from the age of dairy animals at death (e.g., Vigne, 2008) and lipid residue analyses from potsherds (Evershed et al., 2008). Both have shown that dairying was an early feature of European Neolithic economies. By considering ancient DNA data on the occurrence of the –13 910*T* allele in combination with archaeological data on milk use, it appears that dairying was practiced before lactase persistence arose or became common(Burger et al., 2007).

Conclusion

The propensity of our species to colonize a wide range of environments illustrates our species plasticity and adaptability. While much of that plasticity and adaptability is underwritten by our capacity for cumulative culture (Powell et al., 2009), it now seems certain that some biological adaptation has occurred. Our ability to detect the genomic signatures of natural selection has improved dramatically in the last 10 years. This has been simultaneously driven by advances in the molecular techniques used to generate genetic data, by improvements in ancient DNA technologies, and critically, by

innovations in statistical inference and computer simulation modeling. However, challenges remain in disentangling the relative effects of mutation, recombination, migration, population structure, genetic drift, and natural selection on patterns of genetic diversity. Strong evidence for the adaptive status of a trait entails (1) evidence of differential fertility or mortality dependent on particular genetic variation; (2) evidence from *in vitro* and/or *in vivo* studies of functional differences between genotypes that affect the reproductive success of their carriers; and (3) evidence of concordance between the distribution of a genetic traits and the environmental factors that drive selective pressures. Because providing these three types of evidence remains a challenging task, few strong examples of natural selection exist. We have presented two of them, those involving *EDAR* and *LCT* genes.

As molecular techniques improve and become easier and cheaper to perform, more genetic information accumulates, bringing new challenges in handling and analyzing so much data (Pool et al., 2010). With improvements in our understanding of metabolic networks and biological pathways, it becomes increasingly evident that mutations leading to changes in a gene product can affect phenotypes in multiple and subtle ways. This makes the targeting of selective pressure and their potential adaptive consequences difficult. Integrative computational modeling conditioned on multiple data types offers one solution to this problem, and provides a robust means of testing evolutionary hypotheses.

Abstract

Human factors and ergonomics applies scientific information about human cognition and behavior to support the design of products and systems that enhance human well-being and performance. Human factors and ergonomics professionals investigate human–system interaction at the individual, group, and organizational levels. The aim is to design products that augment human physical, cognitive, and motivational capabilities and improve the social, technical, and organizational aspects of a system. Human factors and ergonomics has been used to improve safety and productivity particularly in complex sociotechnical systems.

Introduction

"Everything we invent or make is ultimately designed for human use and benefit" (Chapanis, 1996). As technology and work systems have evolved they have become larger, more complex, and more interconnected. The rate of change in such systems and their increasing complexity have increased the likelihood that unintended and adverse consequences will occur. Human factors and ergonomics has emerged as a profession whose practitioners endeavor to ensure that tools, products, and systems are designed to be safe, usable, and useful for humans. Specifically, human factors and ergonomics is "the scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data and methods to design in order to optimize human well-being and overall system performance" (www.iea.cc; www.hfes.org). According to Dul et al. (2012), human factors and ergonomics is unique because "(1) it takes a systems approach (2) it is design driven and (3) it focuses on two closely related outcomes: performance and well-being" (p. 377).

The scope of human factors and ergonomics work has evolved to be very broad, as shown in **Figure 1**. Human factors and ergonomics work is typically performed at one of three levels of analysis – the individual, group, or organizational level. The individual level of analysis focuses on interactions that an individual human might have with an engineered system, technology, or tool. The group level of analysis focuses on how groups or teams of humans interact with technology and how these interactions influence performance. The organizational level of analysis investigates the influence that organizational design factors (e.g., organizational structure, organizational processes, and work design) and the use of technology have on human well-being and overall productivity. For each of these levels of analysis, human factors and ergonomics professionals draw on knowledge from different disciplines (shown in left column of **Figure 1**) to investigate a range of topics (center column of **Figure 1**) in order to formulate design interventions intended to human–system interactions (right column of **Figure 1**).

In this article, we review the background and scope of human factors and ergonomics work. In the background section, we discuss the origins and history of human factors and ergonomics. We then describe the scope of human factors and ergonomics work in three sections that cover the individual, group, and organization levels of analysis. We conclude the article by outlining some of the future directions and challenges that the human factors and ergonomics discipline faces.

Background

The history of human factors and ergonomics has been traced back to 1857 when Polish scientist Jastrezebowski proposed the term 'ergonomics' to represent the science of human work (Jastrzebowski, 1857[2001]). After the introduction of mass production, the scientific study of human physical labor was reinvigorated by Scientific Management. During this era, scientific studies of labor adopted techniques such as time and motion studies to decompose work into standardized functions that represent the 'best' way for workers to perform a task efficiently and with minimal stress.

The next major change in labor studies occurred during the two World Wars of the twentieth century. In World War I, intense requirements were placed on factory workers which resulted in unacceptable levels of fatigue and injuries (Zionchenko and Munipov, 2005). The responsibility of improving human well-being at work while ensuring high levels of productivity was allocated to specially developed health boards and committees staffed by physiologists, psychologists, engineers, and doctors (Zionchenko and Munipov, 2005).

In World War II, rapid technical advancements changed the nature of human work in a number of ways. For example, newly developed fighter planes required pilots to manage complex cockpits and deal with low oxygen and with high g-forces that they would not survive without supplementary air and special flying suits (Chapanis, 1996). New technology also led to the development of screen-based work including radar and sonar monitoring jobs (Chapanis, 1996). During this time, psychologists, physiologists, and physicians were recruited to work cooperatively with military engineers to create designs that would handle safety and functionality issues associated

Figure 1 Scope of human factors and ergonomics.

with human–technology interactions (Zionchenko and Munipov, 2005).

After World War II, the size and complexity of work systems continued to grow. For example, nuclear weapons technology was converted for use in electricity generation which lead the development of complex, safety critical nuclear power plants. The Three Mile Island nuclear power plant accident in 1979 illustrated the importance of ensuring that industrial systems were built to suit the human operators and controllers. The accident was partly caused by the fact that the system design provided operators with confusing and misleading information that led them to make incorrect decisions (Vicente, 1999). The lessons from Three Mile Island, combined with the proliferation of computerized interfaces in industry, led to the emergence of cognitive systems engineering (Hollnagel and Woods, 1983). Cognitive systems engineering focuses on designing complex sociotechnical systems to facilitate effective and adaptive human diagnosis and control during normal and abnormal operating situations.

As the human factors and ergonomics discipline evolved, its scientists and practitioners began to form into professional societies. Two of the more prominent societies today are the International Ergonomics Association (IEA) and the USA-based Human Factors and Ergonomics Society (HFES). Within these two societies are subgroups that focus on specific aspects and application areas of human factors and ergonomics, such as anthropometry, cognitive engineering and decision making, ergonomics in design, and individual differences in performance. Further subgroups focus on specific applications such as aerospace, aging, healthcare, safety, and transportation. Today, human factors professionals draw on knowledge from many disciplines to take an

evidence-based systems approach to improving human interaction within systems.

Individual Level of Analysis

Much human factors and ergonomics work focuses on the interaction between individual humans and the technical and social systems within which they work. Human factors professionals seek to understand the people who will work in/with the system, the functions people and technology need to perform, and how people might go about performing their required functions. With such an understanding, human factors and ergonomics professionals can help design systems that accommodate the natural variability associated with human performance in ways that help humans achieve the overall system purpose safely and productively while minimizing workplace stress. Studies that investigate interactions between individual humans and sociotechnical systems usually concentrate on *physical ergonomic*s or on *cognitive ergonomics* which will be discussed later. There is also a body of research examining motivational factors.

Physical Ergonomics

Physical ergonomics focuses on designing jobs, tools, equipment, and workspaces to fit the physical attributes of workers. As IEA notes, "physical ergonomics is concerned with human anatomical, anthropometric, physiological and biomechanical characteristics as they relate to physical activity" (www.IEA.cc). Studies involve understanding the capabilities, constraints, and variability associated with the human body in order to design products, processes, and work environments that are productive, safe, and satisfying for people to use (e.g., Ahram and Karwowski, 2013). Physical ergonomics professionals draw on human anthropometrical, biomechanical, and physiological information to design physical environments that accommodate and enhance human sensation and perception, human physical postures, and human musculoskeletal performance (Kroemer and Grandjean, 2009; Marras and Karwowski, 2006).

Sensation and perception are important because they are the processes by which humans receive and process information from their environment (Wickens et al., 2004). Human sensory systems include vision, audition, olfaction, gustation, somasthesis, and the vestibular system. Physical ergonomics professionals aim to design work environments that enhance human sensation and perception and exploit its strengths, rather than harm it. This requires an understanding of how environmental factors such as light, sound, vibration, and temperature can be sources of comfort, discomfort, or even harm to humans. For example, light can help or distract humans depending on the interaction between properties of the light (e.g., the size, luminosity, differentiation, and quality of light), the capabilities, limitations, and variability inherent in the human visual system, and characteristics of the work that the human is required to do. Similarly, human performance can be affected by mismatches among the levels of sound, temperature, and vibration in a system, tolerability limits associated with human senses, and the requirements of the task. Successful physical ergonomics interventions reduce the occurrence of chronic illnesses and impairments (e.g., hearing loss); reduce stress; and improve safety, well-being, and productivity.

Physical ergonomics professionals also investigate the relationships between work space and tool design on the one hand, and human anthropometry, physiological, and biomechanical data on the other. They study how these relationships might affect human safety, health, comfort, and performance (Bridger, 2003). Topics of interest include posture, manual handling, repetitive movements, musculoskeletal workload, and physiological stress and strain. Physical ergonomists aim to produce designs that minimize fatigue, discomfort, musculoskeletal damage, and repetitive strain injuries (Wickens et al., 2004). They perform scientific studies in order to make recommendations on how the design of portable devices, computer input tools, workplace furniture, work station layout, and jobs could be changed to improve user health, safety, comfort, and performance. Examples of some physical ergonomics projects include designing cell phones to suit the attributes of human hands in ways that permits the phone to be operated with one hand only, designing office chairs with the adjustability needed to accommodate the range of human body shapes and sizes, and designing torqueless tools for astronauts working in zero gravity while enclosed in cumbersome space suits.

Cognitive Ergonomics

Cognitive ergonomics focuses on human mental processing abilities and limitations (www.iea.cc). Following the introduction of computerized technology, work has become less physically demanding, and more cognitively demanding. Many tasks place heavy demands on attention, perception, memory, and reasoning. Understanding the strengths and vulnerabilities of human cognitive processes is required to design products, interfaces, and systems that can be used safely and effectively by humans (Hollnagel and Woods, 1983). Cognitive ergonomics draws on knowledge from cognitive psychology, cognitive science, computer science, and control engineering. Cognitive ergonomists seek to design tools and systems based on a scientific understanding of attention, perception, memory, mental models, expertise, and mental workload in order to enhance human situation awareness, problem solving, and decision-making capabilities (Harris, 2013).

Designing systems that enhance human attention and perception is important, because the latter are the processes that collect, filter, and interpret information from the environment. The failure to attend to appropriate cues was a significant factor in Eastern Air Lines Flight 401 crash in 1972 where the entire flight deck crew were so focused on dealing with a faulty landing gear light, they failed to notice that the plane was losing altitude and failed to hear an altitude warning alarm (National Transport Safety Board, 1973). Attention and perception are important components of situation awareness.

Situation awareness has been variously defined. One commonly used definition comes from Endsley (1988) who defines situation awareness as "the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning, and the projection of their

status in the near future" (p. 97). Another definition is that situation awareness is the "continuous extraction of environmental information, integration of this information with previous knowledge to form a coherent mental picture, and the use of that picture in directing further perception and anticipating future events" (Dominguez, 1994). Inaccurate situation awareness has been shown to be a contributing factor to industrial accidents including aviation accidents (Jones and Endsley, 1996) and process industry accidents (Kaber and Endsley, 1998). Hence, creating designs that facilitate accurate situation awareness is a critical prerequisite for ensuring humans correctly respond to situations.

Accurate situation awareness relies, in part, on human memory and so-called mental models. Memory is the human capacity to retain information for future use. Memory is often categorized into working memory and long-term memory (Wickens et al., 2004). Working memory stores limited information on a short-term, temporary basis so that it can be referenced and manipulated. Long-term memory stores information and its relevant associations on a more permanent basis. The term 'mental models' (Gentner and Stevens, 1983) refers to a person's mental representation of a system or object that includes its purpose and descriptions of how it functions and behaves. Mental models are useful constructs to help explain how people comprehend the current status, predict potential future states, and to troubleshoot any issues with a system or product. Inaccurate mental models contributed to the Three Mile Island nuclear reactor incident. Operators believed that an illuminated control panel light for a pressure relief valve indicated that the valve was closed, whereas the light illuminated only when the instruction was given to close the valve and did not indicate the actual physical position of the valve (Sanders, 1998). During the accident, the light was illuminated so operators thought the valve was closed, but it was actually stuck open. This confusion contributed to the accident. Human factors and ergonomics professionals aim to design systems that shape and reinforce accurate mental models so that humans can make correct diagnoses and take appropriate actions in normal and emergency situations.

Human interactions within engineered systems and products usually require them to make decisions and often to solve problems. Decision making is the process that humans use to determine a forward path of action. Problem solving is the mental process used to analyze and resolve problems. To make decisions, people can use different strategies and can be influenced by different biases (Klein, 2009; Kahneman, 2011). For example, people can make decisions using slow and deliberative processes or rapid heuristic processes. These processes can be influenced by biases that can lead to the selection of choices and solutions that are not normatively optimal. Such biases include confirmation bias, hindsight bias, anchoring, and framing effects. Bias in decision making can initiate and escalate situations that lead to accidents. For example, the decision making associated with not redesigning o-rings and then launching space shuttle *Challenger* when the temperature was below 53 °F was found to be a significant factor in the loss of the shuttle and all its crew (Rogers et al., 1986). Confirmation bias was found to be a contributing factor in the misinterpretation of the well integrity test results which, in turn, contributed to the Deepwater Horizon disaster (Hopkins, 2012). Conversely, correct decision making was identified as the first factor that contributed to the successful landing of US Airways flight 1549 on the Hudson River in 2009 (National Transport Safety Board, 2010). Studies that investigate human decision making in real-world contexts are often called naturalistic decision-making studies (Klein et al., 1993). Human factors and ergonomics professionals perform such studies to better understand how to design systems and tools that support human decision-making processes and minimize biases.

Another area of interest to human factors and ergonomics professionals working in cognitive ergonomics is the study of expertise. Human factors and ergonomics professionals seek to understand the cognitive mechanisms, task factors, and environmental situations that contribute to the superior performance that we describe as expertise. One model that is used to understand expert decision making is the Recognition Primed Decision model which suggests that experienced people use their recognition of a situation and prior experience with similar situations to make quick decisions on how to act (Klein et al., 1993). Understanding the factors that can influence the acquisition and execution of expertise can help human factors and ergonomics professionals design tasks and training intended to facilitate the delivery of expert performance. For example, by studying expert land mine detection personnel and using the information to train others, Staszewski (2004) was able to show an improvement in overall detection rates for low metal mines from less than 30% to greater than 80% detection.

Another topic of interest in cognitive ergonomics is that of mental workload. Mental workload is a function of the cognitive demands associated with task performance and of the mental processing ability of the person performing the task (Parasuraman et al., 2008). Performance and safety issues can arise when the cognitive demands of a task exceed the cognitive capabilities of the people performing the task. For example, one of the key factors that contributed to the 1994 explosion at the Texaco Milford Haven refinery was the overloading of control room operators who had to act on 275 poorly prioritized alarms in 11 min and who had to manage a situation using control room displays that did not provide an overview of the process they were controlling (Health and Safety Executive, 1994). Mental workload problems can also arise when the task allocation between humans and automation does not adequately engage human mental processing abilities. Giving automation the responsibility to perform most control functions can leave the human operator with a poor understanding of system functionality and with a low level of control skills that hinder effective human control of events that the automation is not designed to manage (Moray, 1986). For example, the loss of Air France flight 447 with 228 people on board in 2009 occurred when the pilots were unable to effectively manage the plane after the autopilot disconnected at high altitude because the system, including the technology and training provided, was not designed to help the pilots correctly diagnose and manually respond to the unexpected situation (BEA, 2012).

Cognitive ergonomics has also contributed in a number of ways to design safer, more productive systems by improving the design of tools, interfaces, and automated processes that augment the capabilities of individual users. For example, cognitive ergonomics studies were used during the TADMUS

program – a program that was motivated by the 1988 shooting down an Iran commercial passenger airline by the *USS Vincennes*. TADMUS generated a number of design and training solutions to help Navy decision makers correctly identify objects picked up by radar, thereby avoiding such accidents (Cooke and Durso, 2008). To improve interfaces and automated processes, cognitive systems engineers have developed analytic frameworks such as Cognitive Work Analysis (Rasmussen et al., 1994; Vicente, 1999). Cognitive Work Analysis underlies the Ecological Interface Design (EID) approach to designing interfaces and it also guides the allocation of function between humans and automated systems. EID interfaces are intended to support the range of cognition that operators might use to manage anticipated and unanticipated scenarios while controlling complex systems (Vicente and Rasmussen, 1992). EID interfaces have been shown to improve operator problem solving, diagnosis, and control, especially for unanticipated events (e.g., Jamieson, 2007). They have also been shown to be easier to learn and use and more effective in military command and control (Hall et al., 2012).

Motivational Factors

Motivation of the individual worker is not often covered in treatments of human factors and ergonomics because it is conventionally more strongly associated with organizational psychology. Nonetheless, individual motivation is an important factor that has received more attention in, for example, the francophone work psychology tradition, which has contributed ideas to cognitive ergonomics (e.g., Pinder, 2007). Motivational research has examined the role of employee motivation, attitudes, and well-being within sociotechnical systems (Rousseau, 1977). Work and job design are major factors that influence motivation (Campion and Thayer, 1985, 1989). For example, job simplification is a widespread practice, being driven by technological, regulatory, and societal changes. Job simplification involves the proceduralization of work and the removal of autonomy and discretion on the part of the employee. Research has consistently demonstrated that job simplification adversely affects employee motivation and well-being. People need enriched jobs that provide autonomy, variety, and meaning (Pan and Werblow, 2012). In contrast, job enrichment leads to improvements in job satisfaction, productivity, and other employee and business benefits (Humphrey et al., 2007). How worker motivation is ensured during organizational design and preserved during organization change will be covered in the section on the group level of analysis in human factors and ergonomics.

Employee motivation and attitudes are also important during organizational change and when improving occupational safety. Employee motivation and attitudes play a critical role in organizational change. Organizational change initiatives frequently fail due to employee resistance. Similarly, in the area of occupational safety, employee motivation and attitudes play a critical role in determining whether employees will comply with safe work practices and take a proactive approach to safety (e.g., by helping co-workers).

The work done by the human factors and ergonomics community to improve human well-being and system performance at an individual level has more recently been extended to the group and organizational interactions. We discuss the work done at group and organization levels in the next two sections of the article.

Group Level of Analysis

Humans often perform work and interact with systems in groups or teams. For example, in the cockpits of commercial aircraft the captain and co-pilot work together to successfully manage flight operations. Similarly, in medical operating rooms, surgeons, anesthetists, and nurses need to work together to ensure the surgical procedure is successful. As a result, human factors and ergonomics studies can focus on how groups or teams of humans interact to perform tasks in engineered systems. Human factors and ergonomics professionals draw on knowledge from industrial and organizational psychology, social psychology, sociology, industrial engineering, and other disciplines to investigate how system design influences team effectiveness. Team effectiveness is affected by both individual and group attributes. Individual attributes include the physical, cognitive, and motivational attributes discussed in the previous section. Group attributes include teamwork, shared situation awareness, shared mental models, and group decision making. These will be discussed next.

Human factors and ergonomics professionals are interested in how to design products and systems that enhance effective teamwork. A first important prerequisite of effective teamwork is that team members should understand the objectives of the team, where the team fits with other teams, and the overall organizational objectives. A second important prerequisite is that team members should understand their own and other team members' roles, responsibilities, and preferences. When team members understand the objectives and task demands required of the team as well as the knowledge, tendencies, and attitudes of team members, they are better able to coordinate team activities (Cannon-Bowers and Salas, 2006). A third important prerequisite of effective team work is good communication and coordination. The link between effective teamwork and improved performance has been made in the number of contexts including healthcare (e.g., Wheelan et al., 2003) and aviation (e.g., Leedom and Simon, 1995; Stout et al., 1997). The *Herald of Free Enterprise* sinking which resulted when the ferry left port with its bow doors open is an example of the consequences that can occur as a result having systems that tolerate poor teamwork.

A fourth important aspect of team effectiveness is 'shared' situation awareness. In a study of the process industry, it was found that 50% of operations failures associated with reported incidents were due to failures in shared situation awareness (Bullemer and Reising, 2013). Shared situation awareness has two components: individual team members' situation awareness (described in previous section) and the shared understanding of the situation that is present in the team at a given point in time. The shared understanding of the situation can be affected by the context (e.g., objectives to achieve, resources available), environmental conditions (e.g., climatic or workplace conditions), and temporal elements (e.g., time pressure,

risk levels) (Salas et al., 2006). The quality of a team's shared situational awareness can affect team communication and coordination activities as well as the attitudes of, and demands placed on, team members. Shared situation awareness also depends, in part, on shared mental models. Understanding shared mental models helps reveals (1) the commonality between the mental representations held by team members and (2) how the mental representation of the system is distributed or shared among different team members. As Cooke and Gorman (2006) have noted, by considering both perspectives "it is possible to (1) assess the degree to which each member has positional knowledge or knowledge relevant to his or her own role, and (2) the degree to which each team member has inter-positional knowledge or knowledge pertinent to other team roles" (p. 272). With such an understanding, human factors and ergonomics professionals can advise on ways that system designs can promote effective shared situation awareness and shared mental models within groups and teams.

Group decision making is also a key topic for human factors and ergonomics at the group level. Group decision making differs from individual decision making in that it can be influenced by group biases such as group think, internal conflict, group processes, group ethics, social norms of the group, and the combination of individual member preferences and needs. Understanding group decision-making processes is important because it has been identified as a significant contributing factor in major accidents including the loss of the space shuttle *Challenger* (Rogers et al., 1986) and in the Deepwater Horizon disaster (Hopkins, 2012). By understanding group decision-making processes and influences, human factors professionals can design decision support tools and problem-solving aids that promote more effective group decision making.

Other design outcomes that might result from the group level of analysis include changes to team training initiatives, job design, and team design. For example, crew resource management (CRM) is a human factors-inspired training program that focuses on improving crew performance, coordination, and activity management within a particular context. CRM was initially designed to help pilots work together in cockpits to successfully control airplanes through a variety of flight conditions and contingencies. The success of CRM was highlighted in the investigation report of US Airways Flight 1549 crash landing in the Hudson River which stated that "contributing to the survivability of the accident was (1) the decision-making of the flight crewmembers and their crew resource management during the accident sequence" (National Transport Safety Board, 2010). The principles underlying CRM have been extended to other activities such as maintenance work and to other domains such as healthcare. An example of a human factors and ergonomics-inspired job and team redesign initiative that lead to significant improvements was the redesign of an emergency response organization within a nuclear power plant (Klinger and Klein, 1999). The redesign recommendations included suggested changes to the team composition and emergency response operations room layout which led to fewer people, improved situation awareness, and better response outcomes.

Organization Level of Analysis

Human factors and ergonomics professionals recognize that human well-being and overall system performance can be affected by organizational factors. The study of such factors is referred to as organizational ergonomics or macroergonomics. Organizational ergonomics draws on information from organizational science, management science, complexity science, and sociotechnical systems theory to understand how organizational structures, policies, practices, and processes affect human performance and productivity. The aim of organizational ergonomics is to ensure the organization as a whole is designed to facilitate safe and effective interactions between technological subsystems, personnel subsystems, and the external environment. As Hendrick (2005) has noted, "work systems that are fully harmonized and compatible with their sociotechnical characteristics…can result in synergistic improvements in various organizational effectiveness criteria, including health, safety, comfort, and productivity" (p. 43). Topics of interest include organizational design, work design, and the design of organization-wide processes.

Organizational design is the design of the whole organization and it can be described using three dimensions: complexity, formalization, and centralization (Hendrick and Kleiner, 2002). Complexity is the degree to which organizational subunits are differentiated in function and interlinked by coordinating processes. Formalization is the degree to which organizational processes are standardized. Centralization is the extent to which decision making and authority are concentrated within the organization. Organization complexity, formalization, and centralization influence how work is managed at the team level. These three organizational attributes can also influence the culture and behavioral norms within subunits and teams. The importance of organizational factors on human well-being and overall system performance was highlighted as a significant contributor to the 2000 Walkerton water contamination incident that resulted in 2400 people becoming ill and 7 dying (Leveson et al., 2003) and the 2003 space shuttle *Columbia* disaster which resulted in the loss of the shuttle and its crew (Columbia Accident Investigation Board, 2003). Human factors and ergonomics professionals can investigate and recommend organizational design interventions that promote effective interactions between people and technology at an individual, team, subsystem, and organizational level.

Work design involves determining how to arrange work to enhance employee satisfaction and motivation while delivering organizational quality and productivity requirements. Work design initiatives consider task variability factors, work scheduling factors (e.g., shift rosters, flexible working arrangements), physical location of work, productivity requirements, regulatory requirements, employee safety, and social and motivational needs as well as the needs of other stakeholders. Understanding the influence that work design has on human–system interactions is important when introducing organizational level change. For example, between 50 and 75% of technology implementation projects experience some degree of failure (Umble and Umble, 2002). Some of the reasons for these failures can be summarized as a failure to consider system-wide effects of how the technology impacts

user needs, the current work design arrangements, and the organization's current use of technology. Human factors and ergonomics professionals can use macroergonomic techniques to help ensure that organization-wide change projects enhance effective interactions between work designs, workers, and technology at an organization level (Moro, 2009).

The term 'organizational culture' refers to the shared values and assumptions of the members of that organization, and is sometimes described as 'the way things are done around here'. Culture plays an important role in shaping employee behavior and employee response to new systems and processes. For example, safety management systems are now mandatory in many jurisdictions; however, a safety management system is unlikely to be effective unless there is a culture in which safety is valued and employees feel able to raise safety issues without fear of reprisal (Reason, 1997).

Another area where human factors and ergonomics professionals provide advice is on the design of organizational processes. An example of such an organizational process that is frequently recommended by macroergonomics professionals is participatory ergonomics. Participatory ergonomics, an extension of participatory management, is the process by which employees who are affected by a problem or initiative are involved in identifying the interventions that best suit them and that also help to achieve the organizational objectives. As Hendrick (2005) comments, "the participatory approach has proven to be particularly effective in establishing an ergonomics and safety culture, which sustains performance and safety improvements that initially result from the macroergonomic intervention" (p. 55).

Organizational ergonomics can deliver significant improvements to human well-being and to overall system performance. Hendrick (2005) reported that organizational ergonomics interventions have achieved improvements of 50–90% in productivity or quality. The improvements were obtained by adopting the following macroergonomic criteria for effective work system design (Hendrick, 2005):

1. Joint design. The approach used should be human-centered, where the personnel subsystem is designed jointly with the technological subsystem and the design process involves extensive employee participation.
2. Humanized task approach. The allocation of functions and tasks to humans or machines should first consider human professional, cultural, and psychosocial needs before allocating the function or task to a human or a machine.
3. Sociotechnical systems approach. Consideration and evaluation of an organization's sociotechnical characteristics should be integrated into the process of designing any work system.

Conclusion

The nature of human–systems interaction at the individual, group, and organization level will continue to change as technology, people, and systems themselves continue to change. We conclude this article with a brief discussion on the future challenges and opportunities facing the human factors and ergonomics profession.

The development and expansion of digital technology will continue to create paradigm shifts in people's work and lifestyles (e.g., voice recognition, robotics, and augmented cognition). Such paradigm shifts offer opportunities for new interactive experiences, new social challenges, new types of work designs, and new forms of organization. For example, the research currently being undertaken in 'nano' technologies – molecular scale technologies – could lead to the emergence of nanoergonomics studies that seek to improve human interactions with extremely small (nano-sized) devices and machines (Karwowski, 2006). Human factors and ergonomics professionals will need to stay abreast of technology advances in order to continue to propose design improvements that enhance human well-being and overall system performance.

However, the human factors and ergonomics discipline has traditionally been one that reacts to technology developments and safety issues. The discipline needs to become more proactive in anticipating and driving technology advances. Human factors and ergonomics needs to "try to anticipate how the nature of work will change so that it can both foresee what work will be and propose what work should be" (Hollnagel, 2014). As a field of endeavor, human factors and ergonomics also needs to drive technology advancements by integrating itself into every step in the system lifecycle, from operational needs analysis, to concept development, engineering design, implementation and commissioning, operations and maintenance, and even decommissioning (Chapanis, 1996). To be more proactive, human factors and ergonomics professionals need to concentrate on the initial steps of the system development lifecycle. With early involvement, human factors and ergonomics professionals can help to identify, specify, and help create new technology that aids human well-being and overall system performance, rather than just trying to improve existing technologies. Examples of technologies created from human factors and ergonomics initiatives have begun to emerge especially from the healthcare sector. For example, human factors and ergonomics researchers are developing implantable early warning devices for people who are at risk of having a heart attack (Day and Young, 2012). This work needs to be extended across other industries and to help improve other types of human–system interactions.

Another challenge that human factors and ergonomics faces is the need to continue to work on the positioning of the discipline in relation to science and engineering. As a scientific discipline, human factors and ergonomics has accumulated, and must continue to accumulate, a substantial body of knowledge from systematic studies that relate to human–system integration (Dul et al., 2012). As an engineering discipline, human factors and ergonomics has applied, and needs to continue to apply, the principles and knowledge gained from scientific studies to the specification and design of technology, products, and systems. By continuing to advance on both the scientific and engineering fronts, the human factors and ergonomics discipline will increase its contribution to the design of systems that enhance effective interactions between humans and their environment.

In this article, we have provided a high level overview of human factors and ergonomics. For further reading we recommend the following texts:

Human Genome Diversity Project: History

Joanna Radin, Yale University, New Haven, CT, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The Human Genome Diversity Project was intended to be a large-scale effort to sample and archive human genetic variation. It was initially proposed by geneticists and evolutionary biologists in the early 1990s and was soon met by strong criticism. These criticisms came from multiple fronts, including biological and cultural anthropologists as well as indigenous rights activists and community members. Project organizers, who identified as antiracist and uninterested in reaping commercial benefits, were surprised to learn that many of these critics perceived the project as racist and neocolonial. These concerns led the initiative to falter, particularly in the United States. While the Human Genome Diversity Project did not achieve its original aims, it demonstrated the need to attend to the intertwined ethical and epistemological challenges of investigating human difference in a genomic age.

The Human Genome Diversity Project

The Human Genome Diversity Project (hereafter referred to as the Diversity Project) was intended as a large-scale effort to sample and archive human genetic variation. It was publicly proposed by geneticists and evolutionary biologists in the summer of 1991, as part of an effort to overcome a perceived Eurocentric bias in the Human Genome Project (Cavalli-Sforza et al., 1991).

The Diversity Project was also positioned as urgent. Organizers highlighted the importance of collecting genetic material from indigenous populations who were perceived to be vanishing (Roberts, 1991). Although the Diversity Project was not conceived of as a biomedical endeavor, justifications for the focus on such communities situated them both as normal controls and natural genetic laboratories for the detection of inherited diseases.

Those who supported the Diversity Project were self-described antiracist scientists. They were also disinterested in reaping commercial profits from the enterprise (Reardon, 2005). So, it was an unpleasant surprise for them to be accused of racism, colonialism, and biopiracy.

It is not an overstatement to say that the Diversity Project has been central to the formulation of many social scientists' engagement with past, present, and future horizons of the life sciences. At stake in social scientific interest in the Diversity Project are several interrelated questions: Who gets to speak authoritatively about what it means to be biologically human? Who are the bodies from which such biological understandings are built? And, who can benefit from that knowledge?

Antecedents

In accounting for why Diversity Project organizers were caught off guard by criticism of their initiative, it is important to recognize that their proposal was not without precedent. Attempts to map 'human biodiversity' preoccupied nineteenth-century anthropologists and eugenicists (Marks, 1995a). Those projects focused primarily on morphology; that is, what could be seen from looking at or measuring a body or a bone. This emphasis on what could be seen with the naked eye began to shift in the twentieth century with the rise of serology, which depended on the detection of blood groups and immunological markers (Silverman, 2000). An increasingly molecularized view of human difference gained momentum after World War II as these serological techniques were applied in view of the new science of human population genetics.

Population genetics was the interwar product of what has been called the 'evolutionary synthesis' in biology, which reconciled Darwinian ideas about evolution with Mendelian concepts of inheritance (Provine, 1971). Much of the initial mathematical theory of this approach was worked out through the study of observable traits in small interbreeding groups of nonhuman organisms, like fruit flies. Soon, however, interest grew in attempting to extend the techniques of population genetics to humans (Smocovitis, 2012). In the wake of genocide legitimated by Nazi racial science, the quantitative approach of population genetics appeared to provide a more politically neutral and objective approach to the study of human difference.

In 1950, Theodosious Dobzhansky, a leading fruit fly population geneticist, and Sherwood Washburn, a prominent physical anthropologist, brought together colleagues in both fields for a meeting to outline strategies for implementing a research program in human population genetics (1950). The meeting was held at Cold Spring Harbor Laboratories on Long Island. It was there, at the site of the Eugenics Record Office from the 1910s to the 1940s, that the value of a human population genetics focused primarily on geographically isolated and so-called primitive populations was emphasized.

Many of the ideas presented at the 1950 Cold Spring Harbor Symposium were put into practice by attendees who were subsequently affiliated with the ecologically oriented International Biological Program – an ambitious effort to take stock of the biosphere – which ran from 1964 to 1974. Under the auspices of the International Biological Program's Human Adaptability arm, population geneticists and anthropologists began to collect genetic material, including blood, from various populations, especially those they identified as 'primitive' and on the verge of disappearing (Santos, 2002). Although they also gathered a range of measurements and

materials, many believed that the study of blood samples using old serological and new biochemical techniques would provide more objective evidence for the characterization of genetic variation in humans. Instead of looking for observable traits, they could use serological and other biochemical techniques to locate variability in the blood and then use mathematical analyses to extrapolate frequency and patterns of inheritance. These scientists also believed that it was important to preserve the blood they salvaged, such that it could continue to be studied as new molecular techniques were developed. Unprecedented access to technologies of cold storage and air travel greatly facilitated the stockpiling of hundreds of thousands of blood samples (Radin, 2013).

Although the Human Adaptability arm of the International Biological Program was relatively uncontroversial, at least compared to the Diversity Project, it would be inaccurate to say that it did not receive any criticism at all. At the time of its planning, certain human biologists criticized the International Biological Program's focus on 'primitive' groups, pointing to the growing sense that such classifications were illusory and even racist. Other anthropologists, while not opposing the study of such communities per se, were disdainful of geneticists' encroachment into the sites of their fieldwork. Geneticists, they often complained, relied on anthropologists to do the important work of learning family histories and gaining trust, but did not repay those contributions with coauthorship credits.

Luca Cavalli-Sforza, who would become a leader in the Diversity Project, was a participant in the blood collection efforts of the Human Adaptability arm of the International Biological Program, at times relying on the expertise of a cultural anthropologist named Colin Turnbull. The criticism Cavalli-Sforza faced in the 1990s for having proposed a project that was so similar to the stocktaking work of the International Biological Program presented challenges that he was unprepared to effectively negotiate (Santos, 2002). While the seeds of this pushback had already been sown in the 1960s, it was amidst a tighter coupling of science, medical markets, and global communication that they began to bear bitter fruits (Lewin, 1993).

Initial Controversy

The planning for the Diversity Project was structured by a series of three meetings funded by the National Science Foundation and the Department of Energy. (The latter grew out of the Atomic Energy Commission, which had long been interested in studying the impact of radiation on the human genome, including during the International Biological Program.) During this planning stage, the Diversity Project was criticized by a number of groups.

Among those who spoke out against the proposed Diversity Project were biological anthropologists who had training in population genetics. They were mistrustful of an effort that sought to understand human diversity but that failed to explicitly include anthropologists, especially those whose careers had been devoted to the genetic bases of human evolution and variation (Marks, 1995b). Cultural anthropologists expressed mistrust as well. Some of their concerns pertained to the categorization of indigenous peoples as 'primitive' and therefore closer to nature. They viewed this as a form of essentialism that perpetuated rather than overturned a long history of scientific racism. Still other critiques expressed concern about the potential for indigenous peoples to be subjected to a new extractive form of colonialism linked to an emerging biotechnology industry (Lock, 1994; Hayden, 1996; Haraway, 1997).

The Diversity Project also received criticism from outside academia. The first such criticisms were leveraged by an activist group called the Rural Advancement Foundation International (RAFI). RAFI had been vocal on issues of intellectual property and biodiversity for a number of years, although they had previously focused on agricultural issues. RAFI leadership contacted a number of indigenous rights organizations, alerting them to the Diversity Project. Drawing connections between plant bioprospecting and genetic sampling of human genetic material, in June of 1993 RAFI charged that Diversity Project organizers were focused on preservation of potentially valuable genetic material at the expense of conservation of indigenous life ways (RAFI, 1993).

RAFI also attempted to establish a link between the Diversity Project and the patenting of indigenous DNA, which Diversity Project organizers vigorously denied as a goal of their effort. At the root of that particular accusation was the recognition of US National Institutes of Health policies that encouraged patenting of innovations resulting from federally funded biomedical research. Although individual participants in the Diversity Project opposed patenting, they were unsuccessful in diffusing suspicion about their relation to commercial interests. A few months later, the Third World Network, an important source of information on the needs and rights of people in the global south, echoed RAFI's call for an immediate halt to the Diversity Project. It was at the end of 1993 that the World Council of Indigenous Peoples branded the initiative with the label 'Vampire Project,' in which Diversity Project organizers were accused of extracting the lifeblood of indigenous peoples for their own benefit (Reardon, 2005).

Old Questions, New Contexts, Unexpected Outcomes

While the Diversity Project's emphasis on collecting blood from vanishing communities was very similar to goals of the International Biological Program, many things had changed in the approximately 20 years between the two initiatives. Among the most significant were the emergence of an indigenous rights movement and the development of new technologies, namely, the ability to amplify and sequence DNA.

Although scientists had long known about the molecular structure of DNA, making sense of it remained an arduous and highly complex task. This changed in the late 1980s with the advent of a technique known as polymerase chain reaction (PCR). It became easier to work with small amounts DNA, which could in turn provide huge amounts of genetic data. Scientists began to thaw blood samples collected during the International Biological Program in an attempt to recover bits of DNA that had been preserved (Merriwether, 1999).

One of the other significant biomedical breakthroughs of that period was a reliance on preserved cell lines that would allow for the continual production of high-quality DNA.

A white blood cell that was 'transformed' into a cell line by being cultured with a virus would continue to produce DNA. Such transformed cell lines came to be referred to as 'immortal,' because they were now able to outlive the bodies from which they were extracted and to be used for unanticipated purposes (Lock, 2001; Landecker, 2007). Improvements in the practice of tissue culture motivated Diversity Project scientists to collect new blood with the intention of extracting, manipulating, and thus maintaining the cells contained within.

New genomic practices and routines such as the reliance on cell lines and use of PCR not only provided a justification for revisiting the study of biological diversity but also contributed to the construction of race (M'charek, 2005; Reardon, 2005).

For example, one of the earliest debates about the Diversity Project actually took place between two of its organizers, Cavalli-Sforza and geneticist Allan Wilson. At the crux of their disagreement was the most appropriate way to determine what would count as a population. Cavalli-Sforza advocated for an approach that had been used during the International Biological Program: the selection of populations based on language spoken, which he believed correlated with genes. Wilson favored an approach that used a grid to sample populations at regular intervals around the globe. Ultimately, concerns about the cost and time involved in implementing Wilson's grid proposal led organizers to remain committed to a mode of identifying populations in terms of language. Any residual resistance was mooted by Wilson's untimely death from cancer in June of 1991.

The idea that the Diversity Project was a 'Vampire Project' or a new form of biologically based colonialism drew on widespread discomfort with the idea that body parts could be alienated from persons yet kept alive (Lock, 2001). It was a concern that was felt deeply and rippled widely, riding the waves of a coalescing indigenous rights movement. The indigenous rights movement built on several decades of human rights work that had contributed to situating identity as a strategic resource in political struggles.

Some of these struggles were articulated in a special 1996 issue of the journal *Cultural Survival Quarterly*, commissioned to respond to the charges RAFI and others had made against the Diversity Project. Jonathan Friedlaender, the then Program Officer for Physical Anthropology at the US National Science Foundation, was asked to serve as a guest editor (Friedlaender, 1996). Friedlaender, who had conducted his first fieldwork in Melanesia during the International Biological Program and who had for many years used blood samples from members of communities in that region to trace patterns of human diversity found himself at the center of controversy surrounding the use of indigenous DNA when he was wrongly accused by RAFI of attempting to patent Melanesian genes.

The special journal issue featured short essays from a range of individuals, including scientists affiliated with the Diversity Project as well as indigenous rights activists and a representative of RAFI. Solomon Island activist Ray Liloqula suggested that there was a lack of alignment in the interests of scientists and the people they sought to study. He stated that "Indigenous people know who they are, where they come from, what genetic traits are in their families, and have always known where they are going. The problem at the present time is having enough knowledge to cope with the newly introduced ways of life, sickness, and social problems, problems associated with new way of economic and political development, and from being exposed to the wider world" (Liloqula, 1996). Aroha Te Pareake Mead, a Maori activist, argued that, "Western science goes to great lengths to de-humanize the humanness or life-force of human genes; hence, terms such as 'specimens', 'materials', 'properties', and 'collections' are adopted as a means to ignore the essence of life contained within … the same perspective is carried over to issues of replication, immortalization, transgenic engineering, and cloning" (Mead, 1996).

Diversity Project organizers working in North America responded to these critiques by attempting to develop a set of ethical practices intended to ensure that people understood the goals of the project and had enrolled of their own volition. This culminated in the drafting of a 'model ethical protocol,' which yielded the idea of group consent (Greely, 1998). From the perspective of these Diversity Project organizers, group consent was an ethically innovative extension of the biomedical practice of obtaining informed consent to participate in research from individuals. However, the assumptions embedded in the well-intentioned ideas of group consent and research partnership sparked new concerns that directed criticisms back to the epistemological foundations of the project and its focus on populations (Reardon, 2005).

The model ethical protocol also attempted to recast indigenous peoples as research partners. This intervention was received differently both across and within various US communities. Some African-American biological anthropologists felt that any effort to enhance the diversity and participation in the Human Genome Project should also include attention to the genomes of those of African ancestry. In response, Diversity Project organizers sought to expand the list of populations to be studied beyond those seen as rare and endangered to include also African-Americans and Mexican-Americans. At the same time, other African-American biological anthropologists resisted the call for participation, invoking a dark legacy of experimentation, as in the notorious Tuskegee syphilis experiments. Hopi geneticist Frank Dukepoo felt that while some American Indians would willingly participate, many others were likely to perceive an invitation to participate in genetic research as an extension of several centuries of colonization and assimilation (Dukepoo, 1998).

What united all these responses was the concern that despite efforts to make the Diversity Project more inclusive, organizers would retain the authority to define the key questions guiding the research. Those questions might not be those of greatest interest to various participants and, perhaps more insidiously, their answers might produce new kinds of racially tinged harms.

Ultimately, these criticisms caused the Diversity Project to falter in the United States. Yet, in the European Union, laboratories were created to support the study of European genetic diversity. Eventually, the US National Research Council recommended that a small number of research projects be funded. Consortia for the creation and storage of cell lines were also established.

In April 2002, under the rubric of the Human Genome Diversity Project, 1064 cell lines made from the human tissues of individuals and population from around the globe were made available via the Fondation Jean Dausset Centre pour

l'Etude du Polymorphisme Humaine (CEPH) in Paris, France (Cavalli-Sforza, 2004; Cann et al., 2002). The cell lines were collected from various laboratories by the Diversity Project and CEPH and frozen on liquid nitrogen "to provide unlimited supplies of DNA for studies of sequence diversity and history of modern human populations" (Cann et al., 2002). DNA extracted from these samples has been circulated to over 100 researchers leading to more than 200 scientific papers (CEPH, 2000).

A significant portion of this research has been done under the auspices of the International Haplotype Map (also known as the HapMap), begun in 2002 as a public–private effort to link population-based variability to studies of complex diseases like diabetes, cancer, or heart disease (Gibbs et al., 2003). HapMap researchers used cell lines stored at CEPH and also created new ones from populations classified in terms of 'geographical ancestry' as Asian, European, and African. Although HapMap's organizers attempted to define the undertaking in opposition to the Diversity Project, this mode of delimiting populations inspired similar critiques, including concern about the reification or reinscription of race (Fujimura and Rajagopalan, 2011; Duster, 2006). Geographical ancestry appeared to be merely a new way of tracking older and potentially stigmatizing ideas about race (Hamilton, 2008).

Legacies

It is perhaps more meaningful to conclude that the Diversity Project achieved goals that were different than those proposed by its organizers than it is to conclude it was a failure. As one important commentator has observed, the debates sparked by the Diversity Project raised "questions about how to order and classify an aspect of nature to advance human understanding [which] proved inseparable from an allied set of questions about how to organize human differences for the purposes of creating credible and legitimate systems of governance" (Reardon, 2005: p. 3). The political dimensions of these debates were not only enacted in meetings and publications but in the laboratory as well. In the words of another influential commentator, "genetic diversity is not an object that lies waiting for scientists to discover, nor can it be treated as a construct of scientists. Genetic diversity is enacted in a complex scientific practice. It is not only dependent on the scientist and the DNA but also on the various technologies applied to produce it" (M'charek, 2005: p. 4).

These social scientific critiques of the Diversity Project were a result of bringing the practices of cultural anthropology – namely, ethnography – to a new kind of field site: the anthropological genomic laboratory and its allied sites of knowledge making. This reconfiguration of expertise has had the result of making cultural anthropologists, who had been largely excluded from the planning stages of the Diversity Project, newly relevant. It has also resulted in calls for novel biocultural approaches to the study of what it means to be human in the field of Science and Technology Studies as well as in Anthropology (Fullwiley, 2011; Palsson, 2008).

Despite the forces that derailed the Diversity Project in the 1990s, indigenous people – who have not, in fact, disappeared – continue to be the focus of human genetic diversity mapping projects. In addition to the HapMap, in 2005, National Geographic in partnership with the Waitt Family Foundation and IBM launched the Genographic Project. Led by population geneticist Spencer Wells, a student of Cavalli-Sforza, this effort aimed to continue the project of collecting genetic material from groups who were once again cast as vanishing. Like the Diversity Project, and the International Biological Project before it, the Genographic Project trades on notions of endangered diversity to encourage the salvage of genetic material from members of supposedly vulnerable indigenous communities (Tallbear, 2007). That such projects continue to be formulated and funded make clear that lessons of the Diversity Project are still unfolding, generating unexpected challenges for the natural and social sciences, alike (Kowal et al., 2013).

Human Genome Project: History and Assessment

Hub Zwart, Radboud University of Nijmegen, Nijmegen, The Netherlands

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The *Human Genome Project* (HGP) has been hailed as an important milestone in the history of science, in the history of humanity even, and as a project whose completion would not only transform the practice of medicine, but change forever the course of human history as well. By setting up a flanking program devoted to anticipating and addressing the ethical, legal, and social implications of genomics, the HGP has had a substantial influence on the social sciences and humanities fields involved in studying contemporary science as well. In this article, the HGP is first of all placed in a historical perspective (as a key chapter in the history of the life sciences as such). As to the history of the HGP proper (1990–2003), three stages are distinguished. Finally, the author assesses what the impact of the HGP has been, both for the life sciences as such and for the society in a broader sense. Although biomedical benefits (in the form of new treatments, etc.) have been sparse (in comparison to the stellar expectations of the early years), the HGP did change the way we think about ourselves and our own history: Its 'cultural' relevance has been quite significant.

Introduction

The *Human Genome Project* (HGP) has been hailed as an important milestone in the history of science, in the history of humanity even, and as a project whose completion would not only 'transform the practice of medicine' but 'change forever the course of human history' (Davies, 2001/2002, p. xiii). It was argued that, due to the HGP, the 'childhood of the human race is about to come to an end' (Davies, 2001/2002, p. 10). It is biology's version of the Manhattan Project, or, as its Director Francis Collins phrased it in 1993, the HGP is 'more important than putting a man on the moon or splitting the atom' (Davies, 2001/2002, p. 69). From a history of biology perspective, the HGP (whose imminent completion was announced at a Press Conference in June 2000) has been described as the completion of the 'century of the gene' (Fox-Keller, 2000) that began with the rediscovery of the work of Gregor Mendel in the spring of 1900, while the complete sequence became available in 2003, exactly 50 years after the discovery of the structure of DNA by James Watson and Francis Crick. Many have argued that the HGP represents a 'paradigm shift' in biology (Gilbert, 1991), dramatically changing the manner in which biomedical research is done (Collins, 1999). 'Gene hunting' gave way to a much more systematic and data-driven approach. ('Data driven' describes a form of research that, rather than relying on the conscious designing of experiments to test hypotheses, relies on amassing large amounts of data that can be systematically analysed, browsed, and trawled with the help of computer programs looking for patterns and associations.) Enormous amounts of sequencing data were assembled in large-scale databases, allowing for a more comprehensive analysis of living systems.

Besides a series of high-impact papers in top journals such as *Nature* and *Science* (notably International Human Genome Sequencing Consortium IHGSC, 2001, 2004; Venter et al., 2001), the project has unleashed a cascade of publications of breath-taking proportions, covering various genres (research articles, books, comments, interviews, etc.), not only in the life sciences, but also in the social sciences and the humanities. In this article, this quickly expanding library of HGP discourse can only be analysed in brief outline. It will consist of three parts. The central part entails a concise history of the HGP in which three stages will be distinguished. Yet, as the HGP can only be properly understood against the backdrop of previous developments that evolved in the course of the twentieth century, the history of the HGP proper will be preceded by a brief 'prehistory' in which the main events that lead to the launching of the HGP are outlined. The third and final part will be devoted to assessing the meaning and significance of the HGP in retrospect. How do we assess its importance, both for the life sciences as such and for society at large? Seen from this perspective, the HGP no longer functions as an end point (i.e., the completion of century of the gene), but rather as a point of departure (for next generation genomics and other postgenomics developments such as systems biology and synthetic biology).

Prehistory: The Century of the Gene

Michel Foucault's inaugural lecture as Professor of the History of Systems of Thought at the Collège de France (Foucault, 1971) contains a brief but interesting reflection on Gregor Mendel. How could it be, Foucault asks his audience, that Mendel's work, his 'truth,' was more or less completely ignored by the biologists of his time? For Foucault, Mendel was a kind of 'monster' (p. 37), someone who, in 1865, spoke of objects and relied on methods that were completely alien to the biology of his era. In short, Foucault casts him as someone who lived and worked outside established networks, outside official academic discourse: A lost voice who spoke too soon.

A key aspect of Mendel's untimely approach (of his 'epistemic mutation') consisted in the use of a small alphabet of symbols (Aa, Bb, Cc, etc.) to refer to pairs of (dominant or recessive) 'factors,' as he called them (1866/1913), that could be either present or absent in his model organism, the garden pea. What was so rigorously new, according to Foucault, was that Mendel spoke about these factors as autonomous units,

independent of biological categories such as species or sex, as objects of study in their own right. All the rest, everything pertaining to the garden pea as a living organism, was filtered out as it were. For Mendel, *Pisum sativum* was simply a handy research tool for studying what later would come to be called 'genes.' From 1900 onward, this way of looking at the phenomena of life (studying genes with the help of a select number of model organisms that basically functioned as research contrivances, as items in the scientific tool box) came into vogue, and genetics became a core discipline of biology.

In recent decades, this picture of Mendel as a garden monk living in extreme isolation has been revised. There were kindred minds to be found among his contemporaries, who were working and thinking along similar lines. One of them was Francis Galton who, like Mendel, used statistics to study life (Müller-Wille and Rheinberger, 2012). In order to articulate his views on heredity, Galton employed an interesting metaphor:

> Ova and their contents are, to biologists looking at them through microscopes, much what mail-bags and the heaps of letters poured out of them are to those who gaze through the glass windows of a post office … they cannot read a single word of what the letters contain (1875, p. 82).

What Mendel and Galton had in common was the intuition that the basic units of life could be represented as letters of an alphabet. Whenever biologists peered into the nucleus of an ovum through their microscope, they witnessed a process that was comparable to the processing of piles of documents containing characters, but due to the low resolution power of the instruments at their disposal, these documents were as yet unreadable for the scientists of life. Nonetheless, they were written in an alphabet (of a Mendel-like nature) and transferred as it were by ancestors to their descendants (Galton's ovum as a kind of transgenerational communication establishment). In fact, in ancient Greek, the term 'elements' (*stoicheia*) means building blocks and may therefore refer not only to atoms as the building blocks of matter, or to Euclid's building blocks of elementary geometrical knowledge, but also to letters of the alphabet.

One could argue that genomics (the sequencing of genomes, the entirety of an organism's hereditary information, with the help of automated high-throughput sequencing machines) from the very beginning has built on this metaphor. It constitutes an effort to dive deeper into the nuclei of cells, in order to decipher, scan and process these formerly unreadable letters, with the help of the high resolution provided by sophisticated automated sequencing technologies. Thus, the 'century of the gene' (Fox-Keller, 2000), which began with the rediscovery of Mendel's effort to talk about life in terms of a small alphabet of symbols, came to a conclusion with the famous Press Conference of 26 June 2000 when Bill Clinton, Francis Collins, and Craig Venter proudly announced that the HGP was galloping toward completion, producing spates of letters: the human genome sequence, written in the A, C, G, T alphabets the 'code of life.' (ACGT stands for the four nucleic acid bases that make up an organism's DNA. The 'A' stands for adenine, the 'T' for thymine, the 'C' for cytosine, and the 'G' for guanine. These four nucleic acids are the 'letters' of the genetic code.)

The story of what happened between these two poles of the human genome narrative (i.e., the rediscovery of Mendel in the spring of 1900 and the public announcement of the upcoming completion of the human genome sequence in June 2000) is a complex one. Only a few of the major events can be highlighted here.

In the 1930s and 1940s, to begin with, an important transformation took place in the landscape of science. The center of gravity shifted from Central Europe (Vienna, Berlin, and Zürich) to the United Kingdom and the United States, while the academic lingua franca shifted from German to English, and the frontier of the scientific revolution shifted from quantum physics to the molecular life sciences. This transformation was exemplified by two physicists who migrated not only from the German- to the English-speaking world, but also from quantum physics to biology. One of them was Nobel laureate Erwin Schrödinger who, in 1944, gave a series of lectures in Dublin entitled *What is life?* In these lectures, he voiced the idea that the 'genom' (as he spelled it) was basically an 'aperiodic crystal' containing a code comparable to the Morse code. Now that physicists had discovered the elementary building blocks of energy and matter, time had come to use the tested methods and powerful tools of physics (such as crystallography) to unravel the elementary building blocks of life.

At that time, however, Max Delbrück, although younger than Schrödinger, had already put to practice what the latter advocated. He went to Cambridge and later to Caltech in California where he opted for a virus (the bacteriophage) as his model organism. For Delbrück, genes were for biology what atoms had been for physics. And therefore, he began his new career as a biologist by looking for a 'minimal' organism that could somehow play the role that the hydrogen atom had played in quantum physics. This search for the 'hydrogen atom of biology' led to the bacteriophage (literally, the bacteria eater), a virus that attacks and destroys bacteria. He settled upon the phage as his model organism because he wanted to study a living entity that came as close as possible to being 'the gene in itself' ('Das Gen an sich;' Fischer, 1985, p. 98). Thus, Schrödinger and Delbrück played a pivotal role in the emergence of a new field: molecular biology. In fact, the three scientists who in 1962 were awarded the Nobel Prize for their discovery of the structure of DNA, namely, Francis Crick (a physicist), James Watson (a biologist), and Maurice Wilkins (a physicist), had all read (and confessed to be very much inspired by) Schrödinger's lectures, which had been published as a book in 1946, while James Watson took Delbück's course on bacteriophage research at Cold Spring Harbor. Thus, the discovery of the structure of DNA was more or less a direct result of the broader transformation described above: the massive migration of physicists to the new biology (cf Kay, 2000).

Now that the structure of DNA had been revealed, the next big objective was to read and decipher the 'code' embedded in it. After DNA (the double helix), the next big challenge was sequencing the whole genome (the collection of all the genes as well as the noncoding segments present in human DNA). In 1985, Robert Sinsheimer, President of the

University of California, Santa Cruz, and Charles DeLisi from the Department of Energy, organized meetings to discuss the feasibility of sequencing the human genome. One of the first questions to be addressed was whether this would call for a large-scale, international, top–down programmatic effort (Big Science), or rather for a bottom–up, researcher-driven approach. Most participants in the debate tended toward the former and in the course of the 1980s, one of the most ambitious and controversial projects in the history of biology was designed. The final preparations coincided with the collapse of the Berlin Wall and the subsequent reunification of Germany and, to some extent, of Europe as a whole. Euphoria was in the air. On 9 November 1989, as citizens from East Berlin flooded into the Western parts of the divided city, *Nature* published an article on HGP scientists developing a joint database where they could deposit their sequencing materials, flanked by an article about societal issues to be addressed. The project was formally launched on 1 October 1990, with James Watson as its first Director. In 1992, Watson stepped down and was succeeded by Francis Collins while Craig Venter, partly because of his frustrations with the bureaucracy and the power structure of the official HGP, launched a nonprofit, privately funded human genome sequencing project of his own devise. He would establish The Institute of Genomics Research and later Celera Corporation to achieve this goal.

The Human Genome Project: A Concise History

The history of the HGP can roughly be divided into three stages (Zwart, 2008). The first stage (1988–92) was a period of development and implementation, beginning with the appointment of James Watson at the National Institutes of Health (NIH) in 1988 and ending with the latter's resignation (on 10 April 1992). The highlight event was the official launch of the program on 1 October 1990. Simultaneously (also in 1990) a flanking project was launched to anticipate and address the ethical, legal, and social implications (ELSIs) of the sequencing effort, also funded by NIH. In fact, 3–5% of the budget was devoted to this type of research. Thus, NIH became the biggest sponsor of bioethical and other forms of ELSI research in the United States.

The second stage (1993–98) set in with the appointment of Francis Collins (1993) as Watson's successor. The HGP now really gained momentum. For the next few years, work on the HGP came to involve a relatively large number of research groups of varying sizes and sequence capacities. The human genome was divided into 23 natural subunits (the chromosomes) and research labs competed for funding in the context of the NIH peer-review system. By 1998, only 4% of the human genome had been sequenced in this manner. That same year, however, was a turning point in many ways: the onset of the third and final stage (1998–2001).

First of all, former NIH scientist Craig Venter announced that his privately funded Celera Corporation, relying on the latest automated sequencing machines, in combination with his controversial whole-genome shotgun method, would sequence the human genome much faster than the public consortium envisioned (Shreeve, 2004; Venter, 2007). This announcement entailed a direct challenge to the public effort headed by Collins, which was now under the threat of becoming redundant (Cook-Deegan, 1994/1995). The latter responded by formulating a more focused strategy of action. From now on, the bulk of the work would be done by a limited number of big laboratories with massive sequence capacity, such as the Sanger Centre lead by John Sulston (Cambridge, UK) and the Whitehead Institute lead by Eric Lander (Cambridge, Massachusetts): a select number of key players that came to be known as the G-5. Moreover, it was decided that publication of a finished sequence would be preceded by a working draft version, again a departure from the original plan (Davies, 2001/2002, p. 162). Due to this reorientation, the HGP was suddenly transformed into a 'no-holds-barred race to claim the human blueprint.' A dramatic competition ensued, eagerly covered by the media, until on 26 June 2000 the 'race' or 'war' was suddenly declared over, as both sides agreed they had passed the line more or less simultaneously. Collins and Venter cordially made their appearance at the famous press conference at the White House in order to announce, in the presence of President Clinton, that the endeavor to sequence the human genome was nearing its completion . Both teams sealed a truce by publishing working draft versions in a coordinated manner in February 2001, in *Science* and *Nature*, respectively (IHGSC, 2001; Venter et al., 2001), although the fighting between representatives of both 'armies' over who had actually won the race, or war, would continue in various settings until today. Notably, John Sulston continued to question the role of Celera in sequencing the human genome (Sulston and Ferry, 2002/2003).

After 2001, there has been a considerable aftermath. As indicated, the 2001 publication contained a draft version, and the HGP was officially declared complete on 14 April 2003, although a 'final' final version of the finished sequence (with 99.99% accuracy) was published in 2004 (IHGSC, 2004), while further analyses and papers on the HGP continue to occur. The human sequence is now seen as the starting point for future research. This is also visible in the images used to elucidate its meaning (Zwart, 2010). During the Press Conference of June 2000, Collins compared the HGP to the expedition of Lewis and Clark, commissioned by President Thomas Jefferson in the beginning of the nineteenth century to map the western part of North America from the Mississippi to the Pacific. This resulted in a famous map (below, Figure 1) depicting a more or less empty landscape, with a focus on its physical features, such as rivers and mountains. A few years later, when presenting a vision for the future of genomics research (Collins et al., 2003), a different picture emerged (below, Figure 2). Rather than with an open landscape, one is now faced with buildings and emerging infrastructures. The genomics future is envisioned as a three-floor building designed in the style of Frank Lloyd Wright. The basic topology, as it were, has shifted. The landscape has become inhabited. "All the initial objectives of the HGP have now been achieved," Collins et al. argue, "and a revolution in biological research has begun" (p. 835). It will now quickly spread from the basement to biology, health, and society.

Meaning and Significance: Assessing the HGP

One of the questions raised with regard to the HGP has been to what extent it can really be regarded as the advent of 'Big Science' in biology (Vermeulen, 2009). Both Watson and Collins on various occasions placed the HGP on an equal footing with other Big Science endeavors such as the Manhattan Project, the Apollo Program, and the European Organization for Nuclear Research (CERN). The HGP was regarded as 'Big' by many, first of all because of the size of the funding involved (three billion dollars as core funding) in combination with the international scale of the collaboration as well as the fact that the project was managed in a more or less centralized manner by Watson and subsequently Collins as its Director. Yet, Big Science in physics (where the concept first emerged) is typically organized around a centralized large-scale research facility, attracting hundreds of researchers (such as the Large Hadron Collider of CERN in Geneva), whereas HGP's infrastructure remained much more distributed, while its basic technologies were not available from the outset, but were rather developed as the project evolved. Or, as Müller-Wille and Rheinberger phrase it in slightly Marxist terms, the HGP created not only a plethora of scientific products (data, papers, and the like), but also the means for their production (2012, p. 201).

This may be seen as a purely 'semantic' question, but in the context of ongoing controversies and reflections as to what the HGP has been able to achieve, the issue proves quite relevant. Building on the widespread impression that in the end (in terms of benefits for society) the HGP did not quite live up to the stellar ambitions that were voiced in the 1990s, some may now question the viability of a Big Science approach in the life sciences domain as such, whereas others may argue that, in view of the bewildering complexity of living systems, the HGP simply was not Big enough.

This brings us to the second issue over which controversy is still raging: what has been the societal impact of the human sequence? Although it is beyond doubt that genomics has irreversibly changed the life sciences as a global research field, so far, concrete clinical benefits, for instance, in terms of treating cancer, have been sparse. During the 26 June 2000 Press Conference, great expectations were voiced in this respect. Clinton claimed that, because of the HGP, our children's children will probably know the word cancer only as a constellation of stars. Yet, in many ways, the outcomes of the HGP were something of a disappointment. Let me go into this experience of disillusionment in somewhat more detail.

The first major disappointment had to do with the number of genes on the human genome, namely, 22 500, which was an astonishingly low number compared to previous estimates that ranged from 100 000 up to 350 000 (Zwart, 2007). The human genome, moreover, appeared to be quite similar to the genomes of other species, such as the chimpanzee and the laboratory mouse. There is nothing special about our sequence. This in itself constitutes a nice example of what Sigmund Freud (1917/1947) has termed a narcissistic offense. According to Freud, all major scientific breakthroughs (and he mentions the discoveries of Copernicus and Darwin as paradigmatic examples) entail serious narcissistic offenses that challenge our basic views about ourselves. We tend to see ourselves as highly unique and central, but the truth as laid bare by science is that we are not. Yet, we are the only species on earth able and willing to think about our own evolution or about our place in the universe, and we are certainly the only species who has sequenced its own genome (or may come up with such an idea at all). An interesting paradox: food for philosophy indeed. Where does our uniqueness come from?

As we cannot attribute it solely to our DNA, it must come from elsewhere. It must be closely interwoven with our cultural history, over and above our biological evolution. We must be, to a certain extent, manmade. We are not only the producers, but also the products of our technologies, cultures, and societies. It is precisely here that the HGP did have an impact. It has provided us with additional and valuable sources of information concerning early human history, notably by considering not only the human genome itself, but also the genome of others species (such as dogs, horses, rice, cereals, maize, etc.) as historical archives for bioarchaeological research (Zwart and Penders, 2011). In other words, the 'cultural impact' of genomics, by broadening our historical horizon, has been quite significant.

Thus, the experience of disillusionment notably pertained to the biomedical results. While it is widely acknowledged the HGP did have an enormous impact on the way in which biological research is done, its medical applications so far have been quite limited. Although the HGP did succeed in transforming laboratory life, so far the consequences for health care, medicine, and human daily existence in general have been quite modest. This is also reflected in the societal debate triggered by the HGP. Initially, serious concerns were voiced, for instance, by Francis Fukuyama (2002) who believed that the essence of what we are is endangered by biotechnology now that the human sequence is about to be revealed. He postulated the existence of a set of typically 'human' genes, which he termed the Factor X, a genetic endowment that distinguished humankind in essence from other species and should be safeguarded from biotechnological interference. In France, novelist Michel Houellebecq devoted his successful novel *Elementary Particles* (1998) to a scientist who managed to develop an algorithm that allowed humankind to drastically ameliorate its genetic constitution, thereby altering the course of future history (an event on the scale of a 'metaphysical mutation'). Yet, it soon became apparent that such scenarios are fairly unrealistic and that the Factor X is nowhere to be found. A related concern raised in the early days of the HGP was that of genetic discrimination: The idea that human genomics would lead to the emergence of a social underclass of carriers of 'bad genes,' as dramatized in the movie *Gattaca* (released in 1997), for example. Again, these apprehensions, grounded in rather deterministic understanding of the relationships between genes and traits, proved unwarranted. Life is too complex to be understood in such a linear and straightforward fashion. So far, the societal relevance of the HGP has been quite limited indeed. This is also reflected in ELSI research, where big concerns gradually gave way to much more everyday discussions.

In 2010, the journal *Nature* published a retrospective. The basic question was has the proclaimed genomics revolution arrived? Collins (2010a) and Venter (2010) both contributed to the issue. Their answer and that of other contributors was, essentially, not yet. The most important outcome of the HGP resides in the acknowledgment that life is much more 'complicated' (Hayden, 2010) than was envisioned back in 1989, when Francis Collins wrote his very first e-mail and the HGP was about to be launched.

This issue was taken up more elaborately by Francis Collins (2010b) (now Director of NIH) in his latest book *The Language of Life*, written 10 years after the jubilant Press Conference of June 2000. Although he still sees the HGP as 'one of the boldest scientific efforts that humankind has ever mounted' (p. 299), he at the same time acknowledges that the enthusiasm that had peaked during the days of the June 2000 Press Conference has more or less evaporated:

> Nearly a decade has passed since that moment of celebration. Virtually all biomedical researchers would agree that their approach to understanding how life works has been profoundly and irreversibly affected by access to the complete DNA sequence of the human genome … But the effect on the public of all the hoopla in 2000 has been mixed. Most people know that the genome has been spelled out, but they have lost track of what has happened since then. They remember the ascent of the mountain, but they are unaware of the rewards that are starting to appear in the valley. (p. 3)

The revolution is still raging, that is the basic message of his latest book; it is ongoing and societies better prepare themselves for a massive disruptive change, but this will not come through the sequencing of the human genome as such, but rather though its subsequent stage: The era of next-generation sequencing and the $1000 genome (Davies, 2010) and, as a consequence of that, the advent of personal genomics and personalized medicine:

> Healthy individuals are increasingly able to discover some of their body's inner secrets and take appropriate action. The potential for individual prediction is beginning to spill out to the general public, offering the opportunity to take more control of your fate … None of this is happening overnight, [but] without question, man's knowledge of man is undergoing the greatest revolution since Leonardo. (p. 5)

But still, up to this point at least, the transformations brought about by next-generation sequencing are limited. In comparison to the dramatic debates of previous decades, current deliberations focus much more on everyday and perhaps even trivial examples, such as the credibility of providers of personalized genome tests such as 23andMe.

One way of seeing this is to argue that, apparently, supporters of the HGP consciously created a hype in the 1990s, by willfully exaggerating its societal potential. Subsequently, after publication of the human sequence in 2001, they shifted the argument saying that life proved to be much more complex than was expected at the beginning, so that much more research (i.e., much more funding) will be needed to harvest the potential benefits. Another, less cynical, but in my view more credible, way of looking at it is by arguing that a project of the size of HGP is likely to go through a series of stages. From this perspective, Watson and Crick represent the era of childhood and playfulness, building models with toylike components without much regard for formalities, such as research projects or management structures. Subsequently, during the period of latency (the 1970s and 1980s), the focus shifted toward the development of basic tools and skills (such as the Sanger sequencing method) in preparation for a distant and still fairly abstract future. The HGP itself, then, represents the adolescence stage: the era of great expectations and fierce collisions. Finally, at present, human genome sequencing has entered the stage of adulthood and normal science. Genomics

has become embedded in the life sciences and as such, has acquired a certain level of normalcy, so that its implications for human existence are less dramatic, more everyday, perhaps even trivial, and its promises more realistic.

As was already indicated above, a significant impact of the HGP resides in its cultural relevance: The way we see ourselves and think about ourselves as humankind. First of all, genomics provides us with new sources of information, allowing us to revisit early human history in a detailed fashion, from the days of human migration out of Africa up to the emergence and spread of agriculture in the context of the so-called Neolithic revolution. Subsequently, it is clear that the HGP has prepared the ground for, and will gradually be eclipsed by, so-called postgenomic developments, such as personalized genomics (or next-generation sequencing) already mentioned above.

In the early days of the HGP, the human sequence was often presented as the 'blueprint' of human existence or even as 'the near-complete instructions for how to build and run a human body,' downloadable from the Internet (Ridley, 1999, p. 1). Paradoxically, the project that started off as an exemplification of a genetic deterministic mind-set eventually undermined the credibility of precisely the genetic reductionist view of life by revealing the astonishing complexity of living systems. For example, it paved the way for the emergence of epigenetics: the awareness that the vicissitudes of an organism (nurture) may result in modifications of its genome (notably on the level of gene expression), which can be passed on to the future generations. This goes against the long-standing dogma that acquired features cannot be inherited. Another development is the shift from 'reading' (i.e., sequencing) DNA to 'rewriting' DNA on the molecular level, that is synthetic biology: the intermediary zone between genomics and nanoscience. Similar realignments can be discerned elsewhere, for instance, between genomics and brain research (cognomics). Thus, the HGP has definitely strengthened the trend, already characteristic of contemporary technoscience as such, toward the emergence of a plethora of transdisciplinary research conglomerates (molecular biology, bioinformatics, genomics, synthetic biology, epigenetics, cognomics, etc.) by which genomics itself is bound to be engulfed sooner or later.

Human Genomics in Asia

Haidan Chen, College of Humanities and Development Studies, China Agricultural University, Beijing, China
Tikki Pang, Lee Kuan Yew School of Public Policy, National University of Singapore, Singapore, Singapore

Abstract

In the past decade, Asia has been actively engaged in human genomic studies and has made great contributions to the field. There is an increase in the number of genomics institutes, consortiums, and initiatives across the continent to study the association between genetic variation and disease. Despite these laudable efforts, Asia faces tremendous challenges in terms of funding, regulation, collaboration, and ethical, legal, and social issues related to genomics. These need to be addressed in the near future to promote the development of genomic medicine.

Introduction

The past decade has seen the advancement of human genetics and genomics worldwide. Various countries have invested seriously in this field, with the expectation of gaining a better understanding of human health and disease. Biobanks and genetic databases have been built to facilitate interdisciplinary clinical research. Regional and international efforts have also been made to promote the success of genomic medicine. For example, in Europe, the Biobanking and Biomolecular Resources Research Infrastructure has been constructed to secure global competitiveness of research and industry of the European Union, and benefit the health of European citizens. International genomic research collaborations, such as the Human Genome Project (HGP), the International HapMap Project, and the International Cancer Genome Consortium, have produced open-access genetic databases for researchers around the globe (Kaye, 2011; Vaught et al., 2009). The completion of the sequencing of the human genome, the mathematical analysis of DNA variants called single nucleotide polymorphisms (SNPs), and the progress in genome-wide association studies have contributed dramatically to biomedical research. Yet the majority of medical genomics research has mainly focused on people of European descent, the results of which will not be beneficial to the greatest segment of the world's population. Given that the lack of diversity in these studies will bias our understanding of the association between genetic variants and diseases, researchers have recognized the importance of inclusion of populational diversity in pharmacogenomic and genome-wide disease studies (Bustamante et al., 2011).

The geopolitical continent of Asia contains almost two-thirds of the world population, with rich cultural, ethnic, linguistic, and genetic diversity. Asian nations, particularly those still developing, are often depicted as the epicenter of pandemics, e.g., severe acute respiratory syndrome (SARS) and avian influenza outbreaks (Tan et al., 2012). At the same time, these countries also face growing chronic disease burdens, but the causes of diseases in Asian populations remain unknown (Jemal et al., 2011). Thus, genomic research on Asian populations is essential to further enhance our knowledge of the genetic basis of complex chronic and infectious diseases, and to cope with Asian and global public health challenges. In this article, we first give a brief introduction to the contributions of Asian nations to human genomics, placing greater focus on the genomics consortiums and initiatives in the region: Asian Cohort Consortium (ACC), Human Genome Organization (HUGO) Pan-Asia SNP consortium (PASNP 1.0) and HUGO Pan-Asia Population Genomics Initiative (PASNP 2.0). We then discuss the challenges that Asia faces in bringing genomic science and technology to bear on applications of genomic medicine. Finally, we outline several future perspectives for the advancement of genomics in Asia.

Asia's Contribution

The world's largest geopolitical continent, Asia, exhibits heterogeneous geographical, cultural, and socioeconomic characteristics. The investment and progress of genomic science and technology of each country across the continent are uneven. Wealthy countries, such as Singapore and Japan, have made tremendous investments in genomics research and development (R&D) toward efficient diagnosis tools and personalized medicine. The Genome Institute of Singapore (GIS), located at Singapore's biomedical hub, Biopolis, is one of the centers of excellence in genomics in Asia and indeed the world. GIS gained world recognition through its rapid response to SARS and identification of five strains of SARS coronavirus in 2003 to effectively contain a pandemic. The strength of GIS's research lies in three milestone arenas: "infectious diseases, cross-national science diplomacy, and regenerative medicine" (Fischer, 2013). Japan has established several research institutions, e.g., RIKEN Center for Genomic Medicine, and research infrastructures, e.g., Biobank Japan, which are steering the nation ahead on the path toward genomic applications in medicine and health (Yoshizawa et al., 2014).

Emerging economies, such as China and India, are the rising powers in the global biomedicine field and are now challenging the developed economies (Salter and Faulkner, 2011). China was the sole developing country to participate in the HGP, contributing toward sequencing of 1% of the human genome. The Beijing Genomics Institute (BGI) has become a global sequencing powerhouse that sequenced the first Asian human genome, and a number of plant and animal genomes, such as rice, silkworm, chicken, and panda (Normile, 2012). India is endeavoring to foster economic development and address local health needs through investment in genomics-based innovation. The Indian Genome Variation Consortium, a government-funded collaborative network of

several local institutions, is one of the examples that reflect these efforts (Hardy et al., 2012). Still other Asian countries, such as Indonesia and Philippines, have emerged in recent years as active actors in the field of genomics, partly due to their ethnic and linguistic diversity (Liu, 2008). Such efforts by nations across the continent are crucial for Asia's genomic research collaboration networks, such as ACC, APSNP 1.0 and 2.0. We introduce these networks in detail below.

Asia Cohort Consortium

First proposed in November 2004, in Seoul, the ACC is a collaborative cancer cohort research project, involving more than one million healthy people across Asia who will be followed over time until various disease endpoints are reached. The ACC seeks to understand the relationship between genetics, environmental exposures, and the etiology of disease, and to discover early detection biomarkers. The ACC has two missions: "(i) to serve as a platform for cross-cohort collaborative projects and combined analysis and (ii) to act as an incubator for new cohorts" (Song et al., 2012). The ACC has approximately 50 active members from Bangladesh, China, India, Iran, Japan, South Korea, Malaysia, Singapore, Taiwan, and the United States, among others. It is cochaired by John Potter of the Fred Hutchinson Cancer Research Center, Seattle, Washington, USA, and Daehee Kang of Seoul National University College of Medicine, South Korea. Its coordinating center is located at the Fred Hutchinson Cancer Research Center to provide support for scientific collaboration, coordination and communication, data operations, and statistical consultation (Rolland et al., 2011).

As most studies on the associations between body mass index (BMI) and the risk of death have been conducted on North American and European populations, and less is known about these associations in Asian populations, the focus of ACC's projects is on BMI in Asian populations. To date, the cross-cohort collaborative projects of ACC have yielded about seven articles, showing the association between BMI and risk of death; BMI and diabetes; BMI, tobacco smoking, alcohol consumption, and risk of cancer of the small intestine; BMI and risk of death from pancreatic cancer; meat consumption and cause-specific mortality; and BMI and cardiovascular disease mortality in Asian populations (https://www.asiacohort.org/index.html (accessed 03.07.14.)).

PASNP 1.0 and 2.0

The SNP consortium was established in early 1999 through a collaborative effort among major pharmaceutical companies, the Wellcome Trust, and five leading academic centers to provide a resource pool for clinical genomic research and for the discovery of novel diagnosis and personalized therapies (Holden, 2002). This consortium largely focused on Caucasian populations, while genomic variation among Asian peoples remained unexplored. In 2007, HUGO Pan-Asia SNP Consortium (PASNP 1.0) was set up with 93 researchers from 40 institutions in 11 Asian countries to map human genetic diversity in Asia. Coordinated from the GIS, the PASNP took the first steps toward collaboration among Asian scientists.

Based on strong bioinformatics teams from China, India, Japan, Singapore, etc., diverse ethnicities from Indonesia, Malaysia, Philippines, and Taiwan, and the scientists' common interests, the consortium used samples from more than 1900 individuals representing 73 populations to conduct migration studies (Normile, 2004, 2009). The PASNP consortium's first report, published in *Science* in December 2009, provided a physical map of human variation in Southeast Asian, East Asian (EA), and Central South Asian populations, and showed strong evidence for the southern migration route to Asia, though it did not completely rule out a two-wave model of migration (Abdulla et al., 2009).

In order to advance the work of PASNP, the HUGO Pan-Asia Population Genomics Initiative was launched in 2011 as a version 2.0 of PASNP 1.0. It established a larger network with hundreds of researchers, and constructed a gene pool with diverse people, data, and cultures, including those from mainland Central Asia and the Pacific Islands. The goal of PASNP 2.0 is to further explore Asian migration patterns, Asian genetic diversity, and local adaptation, and eventually to translate genomics knowledge to the practice of genomic medicine. The data collected by PASNP 2.0 will be open to the worldwide scientific community for further genomic studies (http://papgi.org/index.php/About_Us (accessed 03.07.14.)).

Despite the achievements that Asian countries and consortiums have made, they still face formidable challenges in terms of funding, regulation, collaboration, and the ethical, legal, and social issues (ELSI) of genomics in Asia. As we show in the next section, the development of human genomics in Asia faces not only similar issues as do other national and transnational endeavors, such as funding, standardization of data and samples, harmonization of ELSI practices and regulations, and gaining public trust, but also some Asia-specific issues and local concerns in the practice of Asian science and collaboration.

Current Challenges

Funding

Funding for genomic science is becoming more competitive and more difficult to obtain, both from the government and from industry sources. For this reason, ensuring sustainable funding is one of the major challenges for genomic studies (Vaught et al., 2009). Even in Singapore, where the government had attracted many top scientists from the West with substantial funds, after two 5-year periods of multibillion dollar investments, with little or no warning the core budgets for bioscience institutes under the Agency for Science, Technology and Research (A*STAR) was cut in the third-year period beginning in 2011. A*STAR bioscientists, including those from GIS, had to compete for grants from the new Industry Alignment Fund, and collaborate with clinicians on industrial and clinical applications (Fischer, 2013; Normile, 2011).

Elsewhere, BGI took an entrepreneurial approach to fuel its growth of sequencing and bioinformatics capabilities. It borrowed 1.5 billion U.S. dollars from a government-owned bank and must begin to pay back the principal within 10 years. Since sequences do not make money, BGI established subsidiary

companies to expand the application of genomic science and technology in order to pay off the debt and generate more income (Normile, 2012). For example, BGI Diagnostics offers health services, such as noninvasive prenatal test and tests for various genetic disorders; BGI Ark Biotechnology Co. LTD has set up a transgenic platform, a cloning platform, an experimental farm, and an animal model department (see BGI's website). In addition to the challenges of funding, some Asian countries also find regulation a problem.

Regulation

When appointed as the first director of the HGP, James Watson resolved that the U.S. National Institutes of Health should allocate part of its funds to study the ELSI of genomics in the face of unprecedented challenges posed by genomics and its future application. Research into the ELSI of genomics was initiated first in the USA, thence spreading to Canada and Europe (Zwart and Nelis, 2009). Awareness of the issues in the East happened much later, but such research was supposed to study similar issues as those in the West for the purpose of some outcomes leading to better regulation of genomics. More recently, Yoshizawa et al. identified heterogeneous regulatory frameworks and ELSI practice among EA countries. They found that EA countries' regulation of genomics had a relatively inconsistent and mixed character. Consider the aspect of privacy as an example: Japan, Singapore, South Korea, and Taiwan have regulations and oversights to protect personal information, while China and Indonesia exert little or no control over privacy issues. A similar situation is seen with ethics review. Even though there are ethics review committees in nearly all of these countries, discrepancies in ethics review capacities and the implementation of oversight between different countries are noticeable (Yoshizawa et al., 2014).

What is perhaps of greater concern is that, in overall terms, there are limited or even absent regulations in many developing countries. Some of these countries may have no or limited capacity to regulate innovative genomic medicine. This could be a major barrier to the application of emerging genomic medicine products to improve global health. Therefore, it is significant to include the developing countries in the International Conference on Harmonization, as well as other international consortia, so that developed countries can help improve the regulatory capacity of developing countries (Hardy et al., 2008). Yet international health research collaboration between developed and developing countries in the field of human genetics is often a sensitive issue.

Biopiracy

There are concerns about possible exploitation of the populations in the developing countries in the commercialization of human tissues, and unfairness in benefit sharing and ownership between developed and developing countries (Schulz-Baldes et al., 2007). Biodiversity-rich countries like China, India, and Indonesia are concerned about the exploitation of genetic resources by more developed countries. They have been uneasy about equitable benefit sharing, ownership, and intellectual property rights in international research collaboration. As a consequence, China promulgated the Interim Measures for the Administration of Human Genetic Resources, issued by its Ministry of Science and Technology and the Ministry of Health in 1998. This directive stipulates that only through collaboration with Chinese parties can foreign researchers get access to Chinese genetic resources (Chen, 2013).

Fearing that Indonesia may not benefit from vaccines developed by international scientists and multinational pharmaceutical companies, the Indonesian government stopped sending H5N1 virus specimens to the World Health Organization in 2006. This stance was supported by Malaysia, Thailand, and other developing countries to communicate their desire for mutual trust, transparency, and equity between the developed and developing nations in the virus sharing mechanism. Moreover, Indonesia revised its health law and enacted the Ministry of Health Regulation on Material Transfer Agreement in 2009 in order to safeguard national sovereignty over its biological materials (Sedyaningsih et al., 2008). Although India has ethical guidelines and regulations in place to prevent biopiracy, there is a lack of adherence to regulations and an absence of strict implementation of measures to monitor the misuse of genetic samples (Kumar, 2009). China faces similar problems. To protect the use of Chinese genetic resources in research collaboration, the Office of Legislative Affairs of the State Council, People's Republic of China, published the exposure draft of Measures for the Administration of Human Genetic Resources online in 2012 to solicit advice from the public. As of this writing, the official measures have still not been issued (http://www.gov.cn/gzdt/2012-10/31/content_2254379.htm (accessed 09.07.14.)). The biopiracy issue reflects complexities in cross-border collaboration as well as the importance of mutual trust and equity among scientists in using human genetics.

Collaboration

Although there are potential dangers of biopiracy and unfair benefit sharing in collaboration between developing countries and more developed countries (north–south collaborations), collaboration should nevertheless be promoted as a strategy to help build developing nations' research and translational capacities (Schulz-Baldes et al., 2007). Increasingly, there is also a trend toward collaboration among developing countries (south–south collaborations) in building human resource capacity (Ivers et al., 2010). In the case of the PASNP consortium, Edison Liu, one of the key organizers of the consortium, found it challenging to coordinate science collaboration among Asian scientists. As he pointed out:

> Scientists in Asia have a tendency to look past each other and focus on collaborations with the United States or Europe, partly because these collaborations get them more credit from their school administrations. Also, in Asia, most countries see each other as competitors. Just getting people together is an accomplishment.
>
> Liu, 2008

The science culture in Asia is different from that among scientists in the West and tends to be more hierarchical and bureaucratic. Another challenge rests with the disparity in research capacities and research infrastructures between Asian

countries (Liu, 2008). Besides these challenges, Asian genomic research collaborations face similar challenges as those of the international science communities more generally. As large-scale genomic research collaborations require data comparisons and validations across different populations, the lack of harmonized ELSI and lack of a regulatory infrastructure for genomic research and application are major hurdles. It is also difficult but crucial to ensure the quality of samples and the interoperability of data for collaboration (Song et al., 2012; Vaught et al., 2009). Finally, the translation of genomics knowledge to genomic medicine and innovative medicine products necessitates the interaction and collaboration of all stakeholders. They are not only scientists, clinicians, policy-makers, and industry people, but also patients, consumers, and healthy individuals.

Publics

Engaging the public in biobank and genomic studies is of great importance because researchers need access to patients' and to the public's biological samples. There are a good number of qualitative and quantitative studies about public perception of biobanks and genetic databases in Western countries to explore the public's reasons for participating and not participating in biobank studies; their views of issues such as informed consent, benefit sharing, commercialization, and internationalization; and their concerns over privacy, discrimination, ownership, and the return of results. However, except for a few limited studies in Asian countries, among them China, Japan, and Singapore, little is known about the Asian public's perception of biobanks (Gottweis et al., 2011).

Investigation of public perceptions of biobanks reveals several factors that affect the public's willingness to donate their samples for research and to participate in the studies. These factors include the public's understanding of biobanks, its trust in research institutions and the scientists running those institutions, and its consideration of privacy, discrimination, and commercialization (Gottweis et al., 2011). In Asia, there is tendency for the public to distrust science. For example, Singapore's growing emphasis on commercialization of science discourages the public's participation in research. In Japan, public trust in expertise was eroded following the earthquake, tsunami, and nuclear accident in 2011 (Arimoto and Sato, 2012). There are cases reporting public distrust of experts, and public concerns over the misuse of genetic information and genetic discrimination after genetic testing in China and South Korea. In Taiwan, tensions and distrust arose between the public and authorities of the Taiwan Biobank due to a lack of open science communication (Yoshizawa et al., 2014). Well-known cases of scientific fraud in South Korea (Bonetta, 2006), Japan (Tsurimoto et al., 2009), and China (Lin, 2013) have also contributed to the lack of trust between the public and scientists. All of these signal a call for an interface of science and society to actively interact with the public.

Future Perspectives

As a result of rich and diverse genetic resources, together with political will of various countries, and the great efforts that scientists have made, Asia is rising in the field of human genomics in the postgenomic era. Building regional collaborative genomics networks, such as ACC and PASNP 1.0 and 2.0, is the first and vital step toward better science, medicine, and health in Asia. The research conducted by these networks is competitive in the global arena and bridges the gaps between Asia and Western countries. However, compared with research collaboration in Europe and North America, Asian genomics networks face more challenges than their counterparts in the West. The emerging economies and the developing countries in Asia have not established consistent and robust regulatory frameworks to govern the conduct of genomic research. Furthermore, their ELSI practice and regulation is often influenced by local sociopolitical and cultural concerns and tends to be heterogeneous. This has been a disincentive to regional collaboration on genomic science and technology, which requires the harmonization of ELSI practice and regulation across Asia. Therefore, in the future, it will be helpful to place more emphasis on research into ELSI of genomics and develop regulatory infrastructures, which could become a tool to secure the public's trust in science. It is also important to encourage both north–south collaborations and south–south collaborations. Experience gained from PASNP could contribute to further collaboration on the basis of previous networks and research collaboration.

Editor's Note

Relevant aspects of genomics research in other countries on the Asian continent are covered in other articles of this Encyclopedia (see cross references). See also e.g. (Najmabadi, et al., 2003; Kumar, 2012; Prainsack, 2007).

Human Language, Evolution of

Josef P Rauschecker, Georgetown University, Washington, DC, USA; and Institute for Advanced Studies, Technische Universität München, Garching, Germany

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Understanding the evolution of language, like that of any other cognitive brain system, benefits from a direct comparison of humans with other living species. Generally speaking, the brains of humans and monkeys show a great deal of anatomical similarity. The auditory cortical system in both species, for instance, is organized into a ventral and a dorsal pathway that originate, respectively, in areas anterior and posterior to a primary field and project to distinct areas of prefrontal cortex. In both species, the ventral pathway performs hierarchical decoding of spectrally complex sounds ('auditory object recognition'), which includes decoding of speech sounds ('speech perception') and their ultimate linking to meaning ('semantics') in humans. The dorsal auditory pathway connects posterior auditory regions in both species with parietal, premotor, and prefrontal cortex and subserves a general function in audiomotor integration and control. This includes processing of auditory space and motion as well as online control of speech. The dorsal stream also concatenates sounds into temporal sequences and has thus developed an important role in sentence processing. Besides these similarities in brain organization, future comparative studies on the evolution of language will have to test whether humans and monkeys show principal differences in brain connectivity (e.g., new pathways appearing as a result of specific mutations) or whether species differences are merely of a quantitative nature. The evidence so far does not seem strong enough to rule out the latter possibility.

Introduction

Great thinkers like Francis Crick have lamented on occasions that "the trouble with language is that there are no animal models." Yet the evolutionary origins of language must be latent in animals living today. Language as complex as in humans may not exist in other animals, but its basic components for decoding sounds within the auditory system, for production of sounds within the motor system, and the sensorimotor coupling between the two should be traceable as precursors of human language in animal models. In addition to these basic elements, working memory and the processing and storage of sequences should be crucial for language systems. The ability to learn the perception and production of communication sounds ('vocal learning') has been considered a critical facet of human language as well and has triggered an important comparison with birdsong (Doupe and Kuhl, 1999; Fitch, 2000; Petkov and Jarvis, 2012). Nonhuman primates, on the other hand, seem to have only a limited capacity for vocal learning, but the neuroanatomy of their cerebral cortex is so intriguingly similar to that of humans that it invites direct comparison as well. The challenge of using the monkey as an animal model for human language consists, therefore, mostly in looking for elements that are underdeveloped compared to humans. The core of this article is built on the assumption that, despite its shortcomings, the brain of nonhuman primates contains sufficiently many similarities with the human brain, so it makes the hypothesis worth considering that something as intricate and unique as the human language system has indeed evolved from simpler versions. Their elements, after some improvement and in combination with each other, might have enabled the evolution of language. Other animal models such as songbirds, considerations of fossile data, and research on nonauditory forms of communication remain of great importance for a complete understanding of language evolution, but are not part of this account.

Species-Specific Communication Sounds in Nonhuman Primates

Spoken language starts with the processing of complex auditory signals. Physiological recordings in nonhuman primates suggest that neurons already at the secondary stage of processing along the auditory cortical pathway (the lateral belt areas; Pandya and Sanides, 1972; Morel et al., 1993) can show a preference for species-specific communication calls (Rauschecker et al., 1995). These findings in rhesus monkeys extend earlier accounts from squirrel monkeys that have also demonstrated vivid responses to species-specific calls at the behavioral and neural level (Winter and Funkenstein, 1973; Wollberg and Newman, 1972). Neuroethologically, it is important to demonstrate such responses to sounds that are specific to communication within the same species; only in this way a system can be established that works for conspecifics and does not respond to signals from other species, as similar as they might be acoustically. It would not make sense, for instance, to expect selective responses to human speech in the brains of monkeys and vice versa. On the other hand, sounds produced in certain behavioral situations, e.g., at the sight of a threat, as 'eagle' or 'snake' alarm calls, might carry distinct semantic meaning triggering specific forms of behavior in members of the same species (Cheney and Seyfarth, 1990).

The response tuning of single neurons (and neuronal assemblies) in nonprimary auditory cortex to species-specific communication sounds is generated by convergence of input from lower order neurons that themselves respond to simple sounds like tones, frequency-modulated sweeps, or band-passed noise bursts. Neurons are sensitive to highly specific combinations of such inputs, and combining signals in a nonlinear conjunctive AND-logic leads to the existence of neurons that respond specifically to certain types of calls. There is every reason to believe that the human auditory cortex contains similar neurons with 'combination sensitivity'

(Suga, 1988; Margoliash and Fortune, 1992), which respond specifically to certain acoustic-phonetic features, syllables, or words. As in the monkey, such a system should be organized into a similar hierarchy from rather simple to more complex neurons, whose incidence increases from primary auditory cortex to more anterior and ventral regions of the superior temporal lobe (Rauschecker, 1998; Rauschecker and Tian, 2000; Romanski and Averbeck, 2009; Kikuchi et al., 2010, 2014; Fukushima et al., 2014) and into ventrolateral prefrontal cortex (Romanski et al., 2005; Cohen et al., 2009).

Human Auditory and Language Cortex

Early studies of human auditory cortex with functional magnetic resonance imaging (MRI) have shown that primary auditory cortex responds best to tones, while at the next stage, the equivalent of the lateral belt in the monkey, band-passed noise bursts are more effective stimuli (Wessinger et al., 2001). Further along the anteroventral pathway, cortical regions are selectively activated by words and intelligible speech sounds (Binder et al., 2000; Scott et al., 2000). This hierarchical organization of the auditory ventral stream with regard to speech sound processing was recently corroborated with more refined imaging techniques (Chevillet et al., 2011). Furthermore, a meta-analysis of more than 100 neuroimaging studies of human speech processing has demonstrated that cortical regions lateral to primary core areas are sensitive to phonemes. Farther afield in the anterior superior temporal gyrus (STG), words are processed; finally, in the most anterior locations of the superior temporal sulcus, short phrases lead to selective activation (DeWitt and Rauschecker, 2012, 2013).

In an exciting series of recent studies (Steinschneider, 2011; Chang et al., 2010; Mesgarani et al., 2014), direct recordings from human auditory cortex have become more feasible. This approach, begun by neurosurgeons in epileptic patients (Penfield and Roberts, 1959; Ojemann et al., 1988), is now utilized with semichronically implanted electrode arrays in electrocorticogram recordings from the cortical surface. Results show neurons in nonprimary human auditory cortex very similar to those described above in nonhuman primates. Most specifically, neurons have been shown to respond to phonetic elements and formant transitions, as one would expect.

Invariance and Categorization of Speech Sounds

Invariant representation of sounds is another important step toward establishing a usable system for auditory communication, such as speech. A particular speech sound has to transmit the same meaning regardless of pitch (fundamental frequency) or loudness and irrespective of idiosyncrasies in the speaker's voice or accent. There is evidence that some invariances are formed along the anteroventral stream (DeWitt and Rauschecker, 2012). Evidence for this comes also from studying the representation of other 'auditory objects' (Leaver and Rauschecker, 2010; Zatorre et al., 2004), i.e., sounds that carry meaning in a wider sense and can form categories of sounds. Speech sounds are only one such category; musical instrument sounds or animal calls would be other examples of categories. It turns out from these studies that the 'speech sound' category is indeed processed in clusters within the same cortical region (anterolateral region of STG in the left hemisphere), whereas musical instrument sounds are processed in a more anterior region of STG in the right hemisphere (Leaver and Rauschecker, 2010). All of this suggests that neurons whose selectivity is generated by combining certain acoustic elements in specific ways cluster together forming invariances and categories. Presumably, similar clustering mechanisms lead to the development of functionally specialized cortical regions that process certain configurations, like faces in the visual domain (Kanwisher et al., 1997) or voices in audition (Belin et al., 2000). Both of these regions exist in humans and nonhuman primates (Petkov et al., 2006), which is a strong argument in favor of a direct evolutionary lineage.

Other reports have found that premotor regions may be involved in the formation of speech sound categories as well (Chevillet et al., 2013), which suggests that the way a sound is produced will also influence the way it is processed and stored. Thus, it appears possible that speech invariances are formed in different ways: First, on the basis of spectrotemporal information, which is pooled along the frequency domain in the sense of an OR-logic within the auditory ventral stream, and second, in the domain of articulatory motor gestures, which are formed originally for speech production, but are invoked during the processing of speech as well. The latter route is reminiscent of the 'motor theory of speech perception' (Liberman and Mattingly, 1985), in that it requires the matching of motor information with spectrotemporal information on the acoustic–phonetic side, but there are two important differences here: neither is the process special for speech nor are the motor gestures alone sufficient for speech perception.

As noted above, the same dual way of encoding information holds for other doable sounds that can be classified into discrete categories (Warren et al., 2005). Such auditory objects are represented in anterior regions of the STG (Leaver and Rauschecker, 2010), but premotor cortex participates in their encoding as long as they can be produced (Scott, 2005). Monkeys are naturally handicapped by their less sophisticated vocal apparatus, which limits their vocal repertoire and their capacity for mimicking sounds (Fitch, 2000). The involvement of the dorsal pathway (including premotor regions) in the processing and categorization of self-produced sounds will therefore have to be tested by other means, e.g., by the monkeys' ability to synchronize with other individuals' cage rattling ('drumming') (Remedios et al., 2009) or by teaching them to produce sound sequences by pressing buttons or leavers rather than their vocal apparatus (Artchakov et al., 2012).

Dorsal Stream for Sensorimotor Integration and Control: Sequences, Sentences, and Beyond

The involvement of the dorsal auditory pathway, including premotor and inferior parietal regions, becomes especially evident, when the encoding and representation of sound sequences is investigated (Leaver et al., 2009). During the learning of such sequences in humans, the basal ganglia are

actively engaged, whereas after the sequences become highly familiar, the same sequences activate increasingly more frontal cortical areas. Analogous findings have been reported in rhesus monkeys (Pasupathy and Miller, 2005). It appears, therefore, that the basal ganglia are responsible for the concatenation or 'chunking' of sequential auditory information. The chunks represent information about conditional probabilities for one sound being followed by another (Rauschecker, 2014). Once the chunks have been formed by basal ganglia action, they are once again stored in prefrontal regions. A similar chunking process occurs with cued sequences of learned finger movements (Koechlin and Jubault, 2006). This process involves prefrontal cortex near Broca's area and has therefore been compared with models of language (Hagoort, 2005), redefining Broca's area in terms of chunking ('unification') of semantic, syntactic, and phonological information. Other accounts have compared Broca's area with a readiness platform, where sequences are put together before they are launched (Wise, 2003). The existence of a homologue of Broca's area in nonhuman primates has been postulated on anatomical grounds (Petrides and Pandya, 2009) and involves similarities in cytoarchitectonics and connectivity (see below). Whether the homology can be backed up in terms of functional and computational mechanisms remains to be seen.

Thus, the role of the dorsal stream, as defined above, can be conceptualized into one of sensorimotor integration and control and applies to all kinds of sequential stimuli, even beyond the auditory domain. Specifically for speech, the dorsal processing stream plays a role in speech production as well as categorization of phonemes during online processing of speech (Rauschecker and Scott, 2009; Rauschecker, 2011; **Figure 1**). The former role conforms to the classical idea of an 'efference copy' or feed-forward internal model (Wolpert et al., 1995) and allows for fast and efficient online control of speech production. By contrast, the latter function can be formalized as an inverse model during real-time speech processing, creating the affordances of the speech signal in a Gibsonian sense (Gibson, 1966; Rauschecker, 2005). Both functions require a direct or indirect connection between sensory and motor cortical structures of the brain, whereby subcortical structures (e.g., the basal ganglia) provide an additional link setting up transitional probabilities during associative learning of sound sequences.

Figure 1 Ventral and dorsal streams for the processing of complex sounds in the primate brain: (a) in the rhesus monkey (Modified from Rauschecker, J.P., Tian, B., 2000. Mechanisms and streams for processing of "what" and "where" in auditory cortex. Proceedings of the National Academy of Sciences of the United States of America 97, 11800–11806.); (b) in the human (Simplified from Rauschecker, J.P., Scott, S.K., 2009. Maps and streams in the auditory cortex: nonhuman primates illuminate human speech processing. Nature Neuroscience 12, 718–724.). The ventral stream (in green) plays a general role in auditory object recognition, including perception of vocalizations and speech. The dorsal stream (in red) pivots around inferior/posterior parietal cortex, where a quick sketch of sensory event information is compared with an efference copy of motor plans (dashed lines). Thus, the dorsal stream plays a general role in sensorimotor integration and control. In clockwise fashion, starting out from auditory cortex, the processing loop performs as a forward model: Object information, such as vocalizations and speech, is decoded in the anteroventral stream all the way to category-invariant inferior frontal cortex (IFC, or VLPFC in monkeys) and transformed into articulatory representations (DLPFC or ventral PMC). Frontal activations are transmitted to the IPL and posterior superior temporal (pST) regions, where they are compared with auditory and other sensory information. AC: auditory cortex; AL: anterolateral area; CL: caudolateral area; STS: superior temporal sulcus; IFC: inferior frontal cortex; DLPFC, VLPFC: dorsolateral and ventrolateral prefrontal cortex; PMC: premotor cortex; IPL: inferior parietal lobule; IPS: inferior parietal sulcus; CS: central sulcus. Composite figure adapted from Rauschecker, J.P., 2011. An expanded role for the dorsal auditory pathway in sensorimotor control and integration. Hearing Research 271, 16–25.

In summary, a system like human language (or its predecessors in nonhuman primates or in a common ancestor of today's humans and nonhuman primates) requires the interplay of ventral- and dorsal-stream systems. Comparing human and monkey brain connectivity, there may be quantitative differences in the strengths of these connections within the dorsal stream, but not a difference in principle (Frey et al., 2008, 2014). Similarly, in the ventral stream, the fine-grain organization of cortical areas and the fine-tuning of its neuronal elements may be richer in humans than in monkeys, providing humans with a perceptual network for the detection of more subtle differences in the acoustic signal. The decisive distinction between humans and monkeys may, therefore, lie in a third component: the prefrontal network, where ventral and dorsal information converges and gets integrated. With its own hierarchical organization, the prefrontal network provides the substrate for recursive processing of nested sequences, as they are typical for human grammatical language structures (Friederici, 2004, 2012). Again, however, this emergent new ability of humans may be based on a quantitative rather than principal difference in human and monkey brain organization, which ties in the existing strengths of both ventral and dorsal processing streams with frontoparietal networks underlying working memory (Bornkessel-Schlesewsky and Schlesewsky, 2013; Bornkessel-Schlesewsky et al., in preparation).

Future Studies

To test the evolutionary similarity of human and monkey ventral and dorsal streams in even greater detail, two things have to be done:

1. Connectivity studies in both species will have to investigate in great detail which areas are indeed connected. This will establish a greater amount of homology than other approaches, especially when the same techniques of structural and functional imaging are utilized. While anatomical tracer studies in monkeys will remain the gold standard (Romanski et al., 1999; Petrides and Pandya, 2009; Hackett, 2011), noninvasive fiber tractography using MRI-based technology will gain increasing importance as its resolution improves, because the exact same approach can be used in both species. Early attempts using diffusion tensor imaging have had insufficient power to resolve crossing fibers within a single voxel or disentangle fibers with crossing trajectories (Anwander et al., 2007; Catani et al., 2005; Croxson et al., 2005; Rilling et al., 2008). Such studies have, therefore, remained inconclusive with regard to monkey–human homologies in language evolution. High-angular-resolution techniques, such as diffusion spectrum imaging (DSI), have been utilized successfully in humans (e.g., Frey et al., 2008) as well as in monkeys (Schmahmann et al., 2007; Wedeen et al., 2008). Cross-validation studies of autoradiographic tract tracing and DSI in monkeys have shown a remarkable concordance of results between tracer studies and DSI (Schmahmann et al., 2007), but further improvements in resolution and reductions in scan time are certainly possible, before such studies can become routine. Functional studies based on blood oxygenation level-dependent responses are feasible in both species as well (Petkov et al., 2006) and can elucidate connectivity to a certain extent. However, microstimulation techniques as another approach to analyze functional connectivity (Petkov et al., in preparation) are limited to animal studies.
2. Behavioral monkey studies have to be designed that test the above concepts and go beyond traditional models of 'what' and 'where' processing. Both of these modes can certainly still be considered as characteristic for the two streams, but as generalized models are developed (Rauschecker, 2011), more appropriate monkey studies will have to follow. These studies will have to focus on the computational transformations that occur between the various processing stages or cortical modules rather than merely the connectivity describing different anatomical pathways. This is how processing streams are really characterized.

Conclusions

In this article, I have argued that the anatomical similarities between the human and nonhuman primate brains are sufficiently close that a quantitative rather than qualitative difference might have resulted in the ability of humans to develop a species-specific communication system into 'real' language. The similarities carry over from audition to speech and form the substrate for language, including those aspects of sentence processing and beyond that are often claimed to require uniquely human computational mechanisms. The ability of monkeys to communicate more effectively might be hampered not only by their less flexible vocal apparatus but by a number of other factors: on the receptive side, denser and more fine-tuned organization of ventral-stream structures for the decoding of complex sounds, more differentiation in higher superior temporal regions that allow better invariance formation, and categorization of auditory objects into fine-grained representations. On the productive side, a similar refinement may have taken place: the ability to produce more intricate, coordinated movements, and, thus, more finely distinguishable sounds, which matched the expansion of perceptual space.

What might have ultimately enabled the evolution of an effective language system, however, might have been the development of a more effective network connecting the ventral and dorsal streams by virtue of a denser, more highly developed prefrontal network. This network, in conjunction with a more effective working memory system resulting from it, would have enabled the combinatorial explosion of vocabulary as well as semantic interpretations, and this would have elevated language to an instrument for communicating abstract thought that was much more limited in nonhumans. This, even more than the ability to learn and memorize patterns of vocal production, might have launched a new era of evolution that ultimately culminated in human language.

Abstract

Language is a uniquely human trait, and yet the need to communicate transcends all species as it facilitates, at the very least, basic survival needs. While human language is unique and without direct comparators, there is evidence for proto-language in animals from birds to primates. Although the characteristics of these forms of communication may not be equivalent to language per se, in this article, we discuss several evolutionary antecedents, or precursors to human language, such as the organization of nervous systems with regional specialization, a mirror neuron system, and the ability to perform manual gestures.

All species on this earth must communicate with each other, whether through vocalizations or gestures, at the very least to facilitate basic survival needs such as sexual selection or alerting conspecifics about the presence of predators. Such intraspecies social communication is a core mediator of survival and natural selection and, as a result, innumerable researchers across a range of disciplines – from sociobiology to cognitive psychology, from linguistics to ecology – have attempted to study, define, and understand social communication. Language, however, is the human capacity to acquire and use complex systems of communication, such as vocal sounds, gestures, or written symbols, to express everything from basic needs to abstract thoughts and feelings. Language then, is a highly complex, rule-based, symbolic means of communication that has allowed humans to maintain complex social structures, to communicate abstract concepts, to share and to anticipate future events, and to convey subtle differences in emotions and intent. It is different from that of other species as our nervous systems have evolved and adapted such that we are not only capable of reasoning with abstraction, but we have also developed a system of communication that enables us to communicate such complex thoughts to each other. However, with the growth of evolutionary psychology, there has been increased evidence for proto-language in animals from birds to gorillas, and while these characteristics may not be considered to be equivalent to human language, they may be precursors to human language.

The complexity of human language has undoubtedly increased over the course of hominid evolution, and although human language is markedly different even from the intricate communication systems exhibited by our closest relatives, the other four extant genera of great apes, there remain elements of speech or communication necessary for human language to exist that are shared by our hominid ancestors, and even by other nonhominid species; elements that are in fact relied on across the entire vertebrate line in order to facilitate communication within species. For example, a key requirement for language is an ability to relate specific vocalizations to individual events or objects (classical conditioning) (Snyder and Harris, 1997). A second precondition for the support of higher cognitive functions, including language, appears to be regional (including inter-hemispheric) specialization of the neocortex. Neuropsychologists, neurologists, neurosurgeons, and practitioners of related disciplines have long studied the causal relations between structural and/or functional cerebral asymmetries and variations in cognitive, motor, and sensory functions. One only has to recall Broca's (1865) recognition of the localization of the motor–speech region for perhaps the best historical example tying speech–motor control to (left-) hemispheric cortical specialization. We now recognize that both handedness and language functions usually co-vary with respect to hemispheric dominance and, hence, anything related to the lateralization of the central nervous system (CNS) (e.g., handedness) also relates to what may be the quintessentially lateralized human brain function – language (Snyder, 2000).

An Asymmetrical Brain

Cerebral lateralization involves the division of information processing across the two cerebral hemispheres and although hemispheric specialization was once considered – even as recently as the 1970s – to be a uniquely human trait, an asymmetrical brain is ubiquitously shared among all vertebrates. One reason for the existence of an asymmetrical brain may be that the advantages associated with possessing such cerebral asymmetry far outweigh the ecological disadvantages associated with lateral biases. It is possible that lateralization may offer increased neural capacity because the specialization of one hemisphere for a particular function ultimately leaves the other hemisphere free to perform other tasks or functions, thus negating the need for duplicate cognitive functions within the two hemispheres (Denenberg, 1981). Another advantage of lateralization is that it may be an efficient way of increasing the brain's ability to simultaneously process multiple sources of information. A classic example of the advantages of lateralization in assisting the simultaneous processing of information is a study conducted in lateralized domestic chicks. A group of domestic chicks were strongly lateralized by exposing the eggs to light before hatching, a condition that can align and strengthen visual lateralization in chicks, and another group was weakly lateralized (i.e., eggs were incubated in the dark).

The chicks were then tested on a dual task that involved the left-hemispheric control of pecking responses and discriminating grain from pebbles, and the right-hemispheric control of monitoring overhead to detect a model predator (Rogers et al., 2004). Strongly lateralized chicks (light-incubated) did not only learn to discriminate between grain (food) and pebble faster than weakly lateralized (dark-incubated) chicks, but they were also able to detect the model predator sooner and were more responsive to the model predator than weakly lateralized chicks (Rogers et al., 2004). Although weakly lateralized chicks often failed to detect the model predator when the chicks were required to also discriminate between grain and pebbles, they had no difficulty in performing this foraging task when no model predator was present, suggesting that strong lateralization is required for chicks to be able to perform two separate tasks simultaneously (Rogers et al., 2004; Rogers, 2000). This advantage of lateralization has similarly been observed in pigeons (Güntürkün et al., 2000), and also in Australian parrots (Magat and Brown, 2009).

Lateralization may also have been naturally selected because it is a convenient way of preventing the simultaneous processing of incompatible responses in organisms with laterally placed eyes, such as the teleost fish (*Girardinus falcatus*). In one of the first experiments to demonstrate asymmetry in lower vertebrates, Cantalupo and colleagues demonstrated that both immature and mature teleost fish showed a bias to turn right when first presented with a simulated predator, but that there was a bias to turn left on subsequent presentations of the predator. The authors speculated that if there were an inborn tendency to monitor for potential predators using the left eye, presumably because the right cerebral hemisphere is selectively involved in emotional expression and control, it is possible that extensive exposure in a particular environment could reduce the strength of that asymmetry (Cantalupo et al., 1995).

Another function that is needed for language is the capacity to build large "vocabularies" of vocal sounds, which is based on the classical conditioning of associations between objects or actions, and vocalizations or speech sounds. This capacity appears to be related to lateral asymmetries for motor control, and also laterally placed nuclei. In a study of 70 African Grey parrots (*Psittacus erithacus*) that are known to exhibit possibly the greatest capacity, in captivity, to develop large lexicons of human speech sounds, right-footed African Greys had significantly larger lexicons than left-footed African Greys, and this difference in lexical size was not accounted for by any differences in training efforts by owners or by socialization with conspecifics (Snyder and Harris, 1997). Although there is a dearth of direct brain lesion studies in parrots – for obvious reasons – this strong relationship between footedness and lexical size in the African Grey is supportive of lesion studies in other bird species. For example, lesion studies in chickens have shown that the intermediate medial hyperstriatum ventrale (IMHV) region of the left hemisphere is involved in both short-term and long-term memory formation and storage, while the right IMHV is more preferentially involved in the initial encoding of memory for future recall (Rogers and Anson, 1979; Cipolla-Neto et al., 1982). Further evidence for hemispheric lateralization of memory formation in chicks also appears in the form of clear changes in synaptic density within the left, but not the right, IMHV (Bradley et al., 1981). Lesion and autoradiography studies of regional differences in CNS metabolic activity have also demonstrated a critical role of the left IMHV in the formation of long-term memory in a variety of learning tasks (Rose and Csillag, 1985; Patterson et al., 1990).

Clearly, the neural substrates of memory formation in the avian brain are complex, and involve regions beyond the IMHV; however, the results of these studies do suggest that the left and the right hemispheres of the chicken brain are specialized for different aspects of stimulus analysis and encoding of information for later recall. Given this, it is possible that one hemisphere of the parrot brain (left hemisphere) is also more involved in the encoding of new words into a parrot's lexicon. Although lexical size is more dependent on the parrot's ability to learn, rehearse, and memorize a novel set of vocal calls that are nonspecies specific, than on motor control, right-footed African Grey parrots are able to better engage in intentional or unintentional classical conditioning to form better associations between their owners' vocal calls and particular events, thus gaining a larger lexicon (Snyder and Harris, 1997). Thus, right-footedness in African Grey parrots may represent a behavioral index of contralateral hemispheric specialization for both motor control and for other 'higher-level' cognitive function, i.e., categorization and long-term mnestic processing of human speech sounds (Snyder and Harris, 1997).

Taken together, there are evolutionary advantages for CNS regional specialization of complex higher cognitive functions, and it is likely that the language evolved as a result of more basic functions that have been conserved across the vertebrate line, such as the ability to engage in classical conditioning and categorical learning. As the mammalian and avian lines diverged about 350 million years ago, it is possible that we are either looking at homologous brain organization as a result of common early ancestor(s). Alternatively, this common pattern of CNS organization between mammals and birds may represent a classic example of convergent evolution. Importantly though, regardless of whether it is homology or convergent evolution, the asymmetric organization of the CNS in mediating higher cognitive functions is likely to be evolutionarily advantageous and suggests that precursors to human language would most likely require a lateralized brain.

Mirror Neuron System

One of the most important cognitive capacities that serves as a prerequisite for the evolution of language, specifically the ability to understand the actions of conspecifics and to both imitate and learn from them, is governed by what is now known as the 'mirror neuron system.' Mirror neurons were first discovered in area F5 of the monkey ventral premotor cortex, and represent a distinctive class of neurons whose activity is modulated when a monkey performs a particular action and when it observes another monkey or human performing a similar action (Di Pellegrino et al., 1992; Rizzolatti et al., 1996). However, mirror neurons only respond when a monkey observes an object-directed action, the mere sight of an object alone is insufficient to trigger activation of the mirror neuron system (Rizzolatti and Luppino, 2001; Rizzolatti and Craighero, 2004). In particular, mirror neurons require some

form of interaction between an effector (either hand or mouth) and an object. The function of mirror neurons has been contested, and they have been implicated in a range of functions from imitation and action understanding, to empathy development. It is likely though, that rather than possessing a unique functional role, mirror neurons subserve a range of neural mechanisms that map visual representations of actions onto their motor counterparts. An important example of this is gesturing as a form of communication in apes, which, as we discuss below, may be a manual precursor to oral language.

As mirror neurons are characterized by their response to both observation and execution of the same action, the human ability to imitate has been proposed to have evolved from the mirror neuron system in monkeys (Arbib, 2005). Indeed, the mirror neuron system has been studied in humans, and while there is no direct evidence of any mirror neurons in humans, functional neuroimaging and magnetic stimulation studies suggest that a similar mirror system exists in humans. One example is a functional magnetic resonance imaging (fMRI) study conducted in normal human volunteers where participants were subjected to two conditions – observation only and observation-execution (Iacoboni et al., 1999). In an 'observation only' situation, participants were only required to observe the stimuli. In the 'observation-execution' situation, the same stimuli were presented but participants were also required to lift their right finger as quickly as possible in response to the stimuli. Interestingly, fMRI showed strong activity in the left *pars opercularis* of the inferior frontal gyrus (IFG), the right parietal region, the right parietal operculum, and the right STS region – but only in the 'observation-execution' situation. Similarly, in another study where human volunteers were required to imitate finger movements that were either goal oriented or actions with no explicit goal, the greatest blood oxygen level-dependent fMRI signal was observed in the *pars opercularis* of the IFG when goal-oriented movements were performed (Koski et al., 2002). This particular activation in the IFG follows a pattern that is consistent with that observed in the area F5 mirror neurons in monkeys, and anatomical studies have suggested that area F5 in the ventral premotor cortex of monkeys is homologous to Brodmann's area 44 in humans (Rizzolatti and Arbib, 1998), which is activated by nonlinguistic motor functions such as gestures and sensorimotor learning (Binkofski and Buccino, 2004) (Brodmann's area 44 differs from area 45 in that area 45 is activated by spoken and signed language (Horwitz et al., 2003)).

An important feature of the neural areas implicated in human language is that they are represented primarily in the left cerebral hemisphere (Hickok and Poeppel, 2004, 2007; Poeppel and Hickok, 2004). This left-hemispheric bias has been proposed to have arisen from the incorporation of vocalization (Corballis, 2010), as vocalization appears to be left hemispheric in nonhominid species such as frogs (Bauer, 1993) and mice (Ehret, 1987). It is important to consider though, that while the primate mirror neuron system can be activated by the sounds of actions, primate vocalizations themselves do not appear to activate this system (Kohler et al., 2002). However, some studies have found that the mirror neuron system in humans is lateralized to the left hemisphere for manual operations unrelated to language. When participants were required to perform a task in which they had to identify pictures of a rotated hand as either a left or a right hand, a task which required participants to simultaneously imagine their own hand rotated to match the pictured hand, activation of the inferior parietal cortex was restricted only to the left hemisphere regardless of whether the pictured hand was a left or a right hand (Sekiyama et al., 2000). Observation of a split-brained patient also showed that only the left hemisphere was activated when the patient engaged in an action observation task, suggesting that any right-hemisphere activation in intact humans (such as that observed by Aziz-Zadeh et al. (2005)) may be a result of data transmission across the corpus callosum from the left hemisphere. Taken together, it appears that in the majority of individuals, the mirror neuron system is predominantly left hemispheric particularly when it pertains to language functions. It is possible then that Broca's area may have evolved on the top of the primate mirror neuron system for grasping (ventral premotor area F5), with its capacity to recognize, imitate, and generate a set of actions, and may indeed even be a reason for the higher prevalence of right handedness in humans (Arbib, 2005; Corballis, 2010).

Gestural Theory of Language Evolution

Given the homology between Broca's area in humans and the ventral premotor area F5 in monkeys, several authors have proposed that language may have evolved from manual gestures rather than directly from vocalizations (Arbib, 2005; Corballis, 2010; Fogassi and Ferrari, 2007; Rizzolatti and Craighero, 2004; Goldin-Meadow, 2005; Rizzolatti and Arbib, 1998). In fact, one does not need to look far to see the intimate relationship between manual gestures and vocal speech. Manual hand gestures are used extensively in people with normal hearing, even in individuals who are blind (Willems and Hagoort, 2007; Goldin-Meadow, 2005), and hand movements are often seen in the early developmental years of young children. For example, babbling in infants is often accompanied by rhythmic hand movements (Masataka, 2001), and word productions in children aged between 11 and 13 months are often accompanied by finger pointing, and gestures that indicate object recognition (Bates and Snyder, 1987; Iverson and Goldin-Meadow, 2005). Finally, language does not necessarily require vocalization. The signed languages of the deaf also have the linguistic complexities and sophistication of spoken languages (Emmorey et al., 2002), and Broca's area has been found to be activated by both speaking and signing (Horwitz et al., 2003).

Neurological research in nonhuman primates have shown that when primates generate vocal calls, the neural circuits activated involve the cingulate cortex, diencephalon, and brainstem structures – circuits that are radically different to those involved when humans speak (Jürgens, 2002; Rizzolatti and Sinigaglia, 2008), and circuits that are more primitive in nature. Further, while vocalizations occur frequently in all animals, the ability to learn vocalizations appear to be restricted to very few nonhuman species, including elephants, seals, killer whales, and some birds, and of the primates, only humans are capable of learning vocalizations (Jarvis, 2006). Attempts to teach human language to nonhuman primates have quickly revealed that primates are unable to produce

anything resembling human language or speech. In perhaps the most famous example, a baby chimpanzee that was reared in a human family was able to articulate only three or four words, and its verbal prowess was very quickly eclipsed by those of the human children in the family (Hayes and Hayes, 1952). However, despite the inability of primates to learn vocalizations, gorillas and bonobo chimpanzees have been found to be capable of socially learning and attending to the communicative bodily gestures of the recipient, both of which are critical to spoken language (Liebal et al., 2004a, 2004b; Pika et al., 2003, 2005). This has led some to argue that the inability to engage in vocal learning and to produce speech may be a result of the limitations of the primate vocal apparatus rather than an inability to produce language itself. Indeed, attempts to teach language to nonhuman primates based on manual gestures have been slightly more successful. For example, researchers at the University of Nevada have taught the chimpanzee Washoe how to communicate using American Sign Language (ASL), and after developing an impressive vocabulary, she was able to combine signs into two- or three-word sequences to perform simple requests (Gardner and Gardner, 1969), making Washoe the first nonhuman to be able to communicate using ASL.

Examinations of food-begging manual gestures and intraspecies communicative exchanges in chimpanzees have revealed a right-hand bias (Meguerditchian et al., 2010; Hopkins et al., 2005). Interestingly, the right-hand preference for species-typical gestures was similar to the right-hand bias directed at humans when requesting for food, but hand preferences for a noncommunicative action (e.g., nose wipe) was not correlated with any communicative hand preference (Meguerditchian et al., 2010). It was thus proposed that as communicative gestures consistently show a right-hand preference, it is possible that chimpanzees, our closest primate relative, may possess a specific left-lateralized cerebral system for communication, and this system may be involved in the production of gestures.

Taken together, while the ability to learn vocalizations is also critical to spoken language, it is possible that this ability occurred much later in the evolutionary path toward human language. Rather, given our primate heritage, our early ancestors might be more likely to have been preadapted to generate spontaneous and intentional communication based on manual and other bodily gestures rather than on vocalizations, and thus, gestural actions in nonhuman primates may constitute an important evolutionary precursor to the emergence of human language.

In considering these aspects, Michael Arbib has proposed seven stages in the evolution of human language that would provide a useful framework of the multitude of evolutionary precursors to human language (Arbib, 2005, 2009).

Stage 1: Grasping and manual gestures or actions that are similarly shared with nonhuman primates.

Stage 2: A mirror neuron system for grasping that can recognize and encode.

Stage 3: An ability to perform simple imitations of object-directed grasping through repeated exposure to stimuli.

Stage 4: An ability to perform more complex imitations for grasping, especially an ability to also recognize conspecifics' gestures as a set of familiar actions and then repeat them, or that the gestures performed may be a combination of novel actions that are approximate to or variants of already familiar actions.

Stage 5: Protosign, which is a gestural-based communication system that formalizes and disambiguates imitations, evolves (e.g., being able to distinguish 'bird' from 'flying,' or 'food' and 'eating').

Stage 6: Protosign would provide the early scaffolding of control mechanisms required for the development of proto-speech, which is the ability to control the vocal apparatus with increasing flexibility until proto-speech becomes dominant.

Stage 7: Language. With a language-ready brain and the capacity to engage in manual–vocal communication, humans gradually shifted from action-object frames to verb-argument structures to syntax and semantics. The increased need for communication in order to survive in a hostile world, coupled with possible intermarriages between groups and tribes who developed separate languages may have thus spurred on the rapid development of human language. It is this final stage that has possibly the least to do with any biological evolution, but may have arisen primarily from cultural evolution and historical change instead.

Genetic and Physical Considerations

It is without any doubt that the emergence of human language has been a result of several quantum leaps in our physiological and genetic structure. For example, the human version of the Forkhead-box P2 (*FOXP2*) gene is functionally identical in all normal human populations worldwide, but differs significantly from our nearest primate relative, the chimpanzee. *FOXP2* in humans and chimpanzees differ by two amino acids – threonine to asparagine substitution at position 303 and asparagine to serine substitution at position 325. This seemingly minor difference of two amino acids has been enough to result in major behavioral and cognitive functions in the lineage of humans. The *FOXP2* gene has been dubbed the 'language gene' as a mutation of this gene in an English family known as the KE family has been found to result in severe deficits in vocal articulation (Belton et al., 2003; Lai et al., 2001). Neuroimaging studies have reported that unlike their unaffected relatives, affected members of the KE family show no activation in Broca's area when they were required to covertly (silently) generate verbs (Liégeois et al., 2003), and significantly reduced gray matter density bilaterally in the caudate nucleus, the cerebellum, and the left and right IFG (Belton et al., 2003) – the cerebral regions that are implicated in both motor and language functions.

Another important factor to consider in the evolutionary path toward human language is the unusual vocal tract of humans. Our descended larynx, the large and rounded shape of our tongue, and the angle between our pharyngeal and oral cavities are fundamentally different to the vocal tracts of other nonhuman species (Lieberman, 1984; Negus, 1949). Lieberman argued that it is this difference that enables humans to produce a greater range of vocalizations and have greater

diversity of formant frequencies. However, cineradiographic observations of nonhuman mammal vocalizations have shown that some mammals lower their larynx during vocalization (e.g., dogs barking) (Fitch, 2005). There are also a number of nonhuman species that have a permanently descended larynx, such as koalas, deer, and lions. These observations suggest then that lowering the larynx to generate more impressive vocalizations (e.g., lion roaring) is a primitive trait, and natural selective forces that are independent of speech may have driven laryngeal descent at some stage in our evolutionary path toward language, and this lowering of the larynx in turn may have acted as a preadaptation for our much later phonetic capabilities (Fitch, 2005).

Conclusions

The purpose of this article was *not* to argue that language runs on a continuum from fish to humans. As discussed above, there have indeed been some dramatic changes in our physiological and genetic structure to allow for human language to emerge. However, despite these important differences between humans and other nonhuman species, there are still some basic requirements that evolutionarily, may serve as precursors to human language, such as an asymmetrical brain, a mirror neuron system, and the ability to perform manual gestures. By themselves, each factor would not be sufficient to produce language as we know it; however, as Charles Darwin would put it, "I cannot doubt that language owes its origin to the imitation and modification, aided by signs and gestures, of various natural sounds, the voices of other animals, and man's own distinctive cries. When we treat of sexual selection we shall see that primeval man, or rather some early progenitor of man, probably used his voice largely, as does one of the gibbon-apes at the present day, in producing true musical cadences, that is in singing; we may conclude from a widely-spread analogy that this power would have been especially exerted during the courtship of the sexes, serving to express various emotions, as love, jealousy, triumph, and serving as a challenge to their rivals. The imitation by articulate sounds of musical cries might have given rise to words expressive of various complex emotions." (Darwin, 1871: p. 56).

Human Mate Choice

Yasuo Ihara, The University of Tokyo, Bunkyoku, Tokyo, Japan

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Human mate choice is partially affected by individual preference for physical or mental characteristics of potential partners. This article examines genetic influences on human mate choice and possible consequences of mate choice on the genetic composition of populations. It considers two examples of physical traits on which human mate choice may depend, namely the human major histocompatibility complex and facial characteristics.

Introduction

Human mate choice could be affected by a myriad of factors. Social norms often encourage or discourage certain types of unions on the basis of kin relations, while individuals may have preferences for certain physical or mental characteristics possessed by potential partners. This article focuses on those aspects of human mate choice driven by individual preferences and briefly reviews some of the recent developments in the field. Firstly, the article discusses the interaction of genes and mate choice in humans. Individual preferences affecting human mate choice may have a genetic basis. More precisely, differences among individuals in mating preferences may be partially accounted for by differences in genes among those individuals. At the same time, mate choice may also have an impact on genes. This is because if individuals mate selectively with respect to traits that are at least partially heritable, that could give rise to nonrandom association of different genes or genetic diversification between populations. Secondly, as an example of a highly heritable physical trait that is relevant to human mate choice, the article considers the major histocompatibility complex (MHC). The MHC plays an important role in the immune system of vertebrates, including humans, and is characterized by its extreme polymorphism so that virtually every individual, except for the case of monozygotic twins, has a different MHC type. Recent studies have suggested that the MHC plays a role in mate choice in humans as well as in nonhuman animals. Thirdly, the article considers a more manifest and partially heritable target of human mate choice, namely facial characteristics. In particular, recent studies have made close examinations to confirm the anecdotal observation that spouses of heterosexual unions resemble each other. Facial similarity between such spouses raises a possibility that individuals may tend to find self-resembling opposite-sex faces attractive and that choice of marriage partners may be affected by this preference.

Genes and Human Mate Choice

One way to explore genetic influences on human behavior is to compare similarities in behaviors of interest within monozygotic (MZ) twin pairs and within dizygotic (DZ) twin pairs, so-called twin studies. MZ twins have virtually identical genotypes, while DZ twins share on average 50% of their genes that are identical by descent. Hence, assuming that the shared environmental effect does not differ between MZ and DZ twins, higher correlation for MZ than DZ twins indicates that behavioral variation among individuals is partially due to genetic variation.

Zietsch et al. (2011) investigated the genetic and environmental influences on mate choice in a large sample of twins and their partners and parents ($N > 20\,000$ individuals), by analyzing key traits potentially relevant to mate choice. There were positive correlations between partners of twins for education, income, religiosity, social attitudes, and age, suggesting that twins may tend to choose similar partners with respect to these traits. However, the correlations were not significantly higher for MZ than DZ twins, indicating no genetic influence on mate choice. These results are consistent with an earlier study by Lykken and Tellegen (1993) based on a smaller sample of twins (152 and 117 pairs of MZ and DZ twins, respectively). In contrast, Rushton and Bons (2005) found that spouses of MZ twins (174 pairs) were more similar to each other than were those of DZ twins (148 pairs) in their responses to personality, attitude, and demographic questions, which was indicative of a genetic influence.

As mentioned in this article, human mate choice is affected by various factors, thus making it difficult to detect genetic influences on 'realized' mate choice. Nevertheless, genetic influences on individual preferences, whether or not they are fulfilled in actual mate choice, may be revealed by asking people what they like. Phillips et al. (2010) asked twin pairs to complete a psychometric scale measuring mate preference toward altruistic traits in a potential mate (MPAT scale; Phillips et al., 2008). Analyzing the sample of 70 MZ and 87 DZ twin pairs (all females), they found a significant positive correlation in the responses to the MPAT scale for MZ twin pairs but not for DZ twin pairs. Hence, the variance in female preference toward altruistic traits is partially explained by the genetic variance. More recently, Zietsch et al. (2012) investigated genetic influences on long-term mate preferences by asking more than 4000 twins to evaluate the relative importance of 13 traits that might be present in a potential mate (Buss and Barnes, 1986): kind and understanding, easygoing, intelligent, healthy, physically attractive, exciting personality, wants children, good earning capacity, creative and artistic, good housekeeper, good heredity, university graduate, and religious. They compared correlations between MZ twins and between DZ twins for the reported relative importance of each trait and found that

correlations were higher for MZ than DZ twins for almost all the traits for both sexes, suggesting widespread genetic influences on mating preferences.

Laurent et al. (2012) analyzed the genome-wide data on single nucleotide polymorphisms (SNPs) in three populations of African, European-American, and Mexican origins from the HapMap 3 database (Altshuler et al., 2010) to detect extreme patterns of genetic similarity or dissimilarity between spouses. The average kinship coefficient, a measure of relative genetic similarity, between spouses was computed for each of 19 979 genes and tested whether it deviated from zero in a statistically significant manner by comparing it against null distributions obtained by randomization procedures. They provided a list of genes that showed significant signatures of nonrandom mating (although most of them did not reach statistical significance under a more stringent criterion). The list included some genes that might influence physical appearance and thus were potentially interesting in the context of mate choice. For example, assortative mating (i.e., a tendency to mate with someone similar to self for a given gene) was detected in the European-American population for MLPH, a gene involved in pigmentation, and PLOD1, a gene associated with epidermis development. Also, in the Mexican population, disassortative mating (i.e., tendency to mate with someone dissimilar to self) was detected for KRT32 and KRT35, two keratin genes involved in epidermis development.

Genes involved in skin appearance exhibited signatures of nonrandom mating in the European-American and Mexican populations but not in the African population: in fact, most of the genes on the list were population specific. As indicated by Laurent et al. (2012), the limited overlap between populations might be due to population-specific mating preferences culturally maintained over a large number of generations. If that is the case, this can be regarded as an example of gene–culture coevolution, where culture contributes to shape the genetic compositions of populations (see Laland et al., 2010).

Human Mate Choice Based on the Major Histocompatibility Complex

The MHC plays a fundamental role in the immune system of vertebrate species. MHC molecules are cell surface glycoproteins whose principal function is to present foreign antigens to T cells to initiate immune response against invading parasites. The extreme polymorphism of the genetic loci encoding MHC molecules is thought to be maintained by such mechanisms as heterozygote advantage, frequency-dependent selection, maternal–fetal interactions, and nonrandom mating (Apanius et al., 1997).

In 1976, Yamazaki and colleagues reported the results of their experiments indicating that house mice apparently have a mating preference dependent on MHC similarity between individuals (Yamazaki et al., 1976). Succeeding studies have confirmed that male and female mice are more likely to mate with individuals having MHC genotypes dissimilar to theirs than with MHC-similar individuals (Egid and Brown, 1989; Potts et al., 1991; reviewed in Penn and Potts, 1999) and that the recognition of MHC types of others is mediated by olfaction (Yamazaki et al., 1979; reviewed in Penn and Potts, 1998). Disassortative mating for the MHC tends to result in MHC-heterozygous and thus immunocompetent offspring as well as inbreeding avoidance. Possible influences of the MHC on mate choice have also been explored in other species of mammals and in birds, reptiles, and fish (reviewed in Piertney and Oliver, 2006).

The possibility that the MHC may be also relevant to human mate choice was first tested experimentally by Wedekind et al. (1995). In their experiment, 44 male university students were asked to wear a T-shirt for two consecutive nights and live as much as possible 'odor-neutral' during these two days. Then 49 female university students evaluated the odors of the T-shirts worn by males who were similar or dissimilar to the females at MHC loci. It turned out that females who were not taking oral contraceptives tended to rate the odors of MHC-dissimilar males more pleasant and sexier than those of MHC-similar males. Furthermore, the odors of MHC-dissimilar males were more likely to remind the females of their current or previous mates than were those of MHC-similar males. In a subsequent experiment by Wedekind and Füri (1997), 121 male and female participants evaluated the odors of T-shirts worn by four males and two females. Consistent with the earlier study, pleasantness ratings given to the odors were negatively correlated with the degree of MHC similarity between smellers (males and females not using oral contraceptives pooled) and T-shirt wearers (males and females pooled). These results seem to support the hypothesis that humans have an MHC-dependent odor preference that may consciously or unconsciously influence mate choice decisions, as in some species of nonhuman vertebrates.

However, further experiments by other research groups have produced mixed results (reviewed in Havlicek and Roberts, 2009). First, Jacob et al. (2002) asked 49 female raters to evaluate the odors of T-shirts worn by six male donors and found that the donor of a female's most preferred odor shared significantly more MHC alleles with her than did the donor of her least preferred odor. This result seems to contradict the previous studies by Wedekind and colleagues, which found a negative impact of MHC similarity on perceived odor pleasantness, although Jacob et al. (2002) argued that the results are consistent if odor pleasantness is maximized for an optimal MHC similarity. Second, in Thornhill et al. (2003), 97 male and 100 female participants provided body odor by wearing T-shirts and also evaluated the odors of opposite-sex participants. For the analysis, data on the odors of 56 males and 48 females rated by 77 males and 65 females not using oral contraceptives were used. Attractiveness ratings given to a female's odor tended to negatively correlate with MHC similarity between the female and male raters, suggesting that males prefer the odor of MHC-dissimilar females. In contrast, no evidence of MHC-dependent preference was found in female raters. Third, Santos et al. (2005) collected the body odor of 29 male and 29 female university students not by T-shirts but by necklaces with a cotton sachet. The male and female participants subsequently evaluated the odors of opposite-sex participants and classified them into three categories: pleasant, indifferent, or unpleasant. MHC similarity was statistically associated with perceived odor pleasantness only in the case when female raters evaluated male odor: more specifically, females were more likely to classify a male's odor

as indifferent when they shared fewer MHC alleles with the odor donor. Fourth, following the original experiment by Wedekind et al. (1995), Roberts et al. (2008) asked each female participant to evaluate the odors of six males who were similar or dissimilar to her at MHC loci. In total, ratings given to the odors of 97 males by 110 females not using oral contraceptives were analyzed. In spite of the nearly identical experimental design, the results of Wedekind et al. (1995) were not replicated successfully: Roberts et al. (2008) found no association between perceived odor pleasantness and MHC similarity.

If humans do have such MHC-dependent odor preference as claimed by Wedekind et al. (1995), it might have an effect on their actual choice of marriage partners. This raises an interesting hypothesis to be tested: married couples may be more dissimilar to each other at MHC loci than expected by chance. Indeed, Ober et al. (1997) provided evidence supporting the hypothesis. They studied 411 married couples in the Hutterites, a North American reproductive isolate known to have limited MHC variation, and found that the number of couples matching for a five-locus MHC haplotype, 44, was significantly smaller than expected by chance. However, Hedrick and Black (1997), who examined the numbers of shared MHC alleles among 194 couples from 11 South Amerindian tribes, did not find any significant deviation from those expected by random mating. Ihara et al. (2000) also compared the observed and expected MHC similarity between wives and husbands for 154 couples from six prefectures in the Tohoku region of Japan and 291 couples from 16 prefectures all over Japan. They too did not find any evidence of disassortative mating for MHC loci (for related studies, see also Havlicek and Roberts, 2009).

MHC similarity between spouses has also been investigated using SNP data. Chaix et al. (2008) analyzed similarity between spouses for 9010 SNPs distributed across the MHC region for 28 couples of European-American origin and 27 couples of African origin from the HapMap 2 data set (Frazer et al., 2007). It turned out that European-American spouses were significantly less similar to each other than were random pairs of individuals, while the similarity in African spouses was not different from that in random pairs. That is, MHC-disassortative mating was detected in the European-American sample but not in the African sample. In addition, when the spousal similarity was examined for more than 3 million SNPs distributed genome-wide, African spouses were significantly more similar to each other than were random pairs, whereas any significant tendency was not observed in European-American spouses. The genome-wide similarity in African spouses – or, more specifically, couples from the Yoruba ethnic group from Nigeria – was interpreted as a result of socio-demographic processes specific to this population rather than individuals' mating preference. More recently, Detri et al. (2010) performed a similar analysis using the HapMap 3 data set (Altshuler et al., 2010), which was not available at the time of the publication of Chaix et al. (2008). Based on their analysis, Detri et al. (2010) argued that the observation by Chaix et al. (2008) of MHC dissimilarity among European-American spouses from the HapMap 2 data set was not robust, and a similar analysis on the HapMap 3 data set did not find such a tendency (for further discussion, see Detri and Roth, 2012; Laurent and Chaix, 2012).

Human Mate Choice Based on Facial Characteristics

Casual observers have frequently noted facial resemblance between spouses, and researchers have shown that this impression is apparently true. In an early experiment by Griffiths and Kunz (1973), participants matched facial photographs of married couples more correctly than expected by chance. Since the result was the same even when photographs were limited to those of couples married less than one year, it was suggested that people tend to marry someone facially similar to them (see also Hinsz, 1987), even if they also grow physically similar after marriage (Zajonc et al., 1987).

More recently, Bereczkei and colleagues have devised a simple procedure to detect facial similarity between individuals (Bereczkei et al., 2002, 2004). Each of their group photos, or 'tableaus,' contained five photographs of different faces, one on the left-hand side and four on the right-hand side. In one kind of tableau, a husband was placed on the left and his wife as well as three control females of similar age on the right. A set of such tableaus was presented to judges, who were instructed to choose one of the four female faces that they thought was most similar to the male face. For their sample of 32 couples, Bereczkei et al. (2002) found that the proportion of judges who chose the photograph of the wife as the most similar to the husband was significantly greater than expected by chance, confirming the findings of earlier studies that spouses tend to be facially similar to each other.

Furthermore, using another kind of tableau, Bereczkei et al. (2002) also examined facial resemblance between a wife and her mother-in-law. This second set of tableaus was motivated by the hypothesis that human mate choice may be influenced by parental phenotypes, learned during the early stage of development through parent–offspring interaction, analogous to the phenomenon known as sexual imprinting in nonhuman animals (ten Cate and Vos, 1999). In a nutshell, they tested whether or not a man tends to be attracted by women who resemble his mother when she was younger. The results of the experiment were as follows: a wife tended to be judged as similar to her husband's mother at the age when the son was between two and eight years old, and the degree of resemblance was even higher between wives and husbands' mothers than between wives and husbands. In addition, according to the husbands' responses to the short form of the EMBU (Swedish acronym for Egna Minnen Beträffande Uppfostran ["My memories of upbringing"]). (Arindell et al., 1999), a self-report scale to quantify one's relationship with the parents during childhood, a wife was more likely to resemble her husband's mother if the husband had been less frequently rejected by the mother during childhood. In sum, these results indicated the existence of a "sexual-imprinting-like" mechanism, by which a man tends to prefer a woman who resembles his mother.

There were two major caveats to the experiment of Bereczkei and colleagues. First, Bereczkei et al. (2002) considered a putative sexual-imprinting-like effect only on male mate choice. Whether or not a woman also prefers a man resembling her father was not investigated. Second, more importantly, the observed resemblance between wives and mothers-in-law might have been created jointly by the wife–husband resemblance owing to a preference for self-resembling partners and the son–mother resemblance due to shared genes, rather than

by maternal influence on the son's mate choice. To deal with these issues, Bereczkei et al. (2004) investigated mate choice of 26 women from adoptive families, in which daughters were not genetically related to their adoptive parents. Using a similar technique as the previous study, they examined facial similarity between husbands and wives, between husbands and wives' adoptive fathers and between husbands and wives' adoptive mothers. As it turned out, husbands were judged as resembling their wives, confirming the previous study. Husbands were also judged as similar to the wives' adoptive fathers (at the age when the daughters were between two and eight years old), while statistically significant resemblance was not found between husbands and the wives' adoptive mothers (when the daughters were between two and eight years old). Recalling that the women were genetically unrelated to the adoptive parents, the observed resemblance between husbands and wives' adoptive fathers could not be a joint result of wife–husband resemblance and daughter–father resemblance. Hence, this result supports the existence of a sexual-imprinting-like phenomenon in humans (see also Little et al., 2003; Wiszewska et al., 2007; but see Nojo et al., 2012; Rantala and Marcinkowska, 2011).

Instead of searching for similarity in the faces of established couples, another line of studies has directly investigated people's preference for self-resembling faces. For this purpose, researchers have used computer graphic techniques to generate same- or opposite-sex facial images resembling experimental subjects in a subtle way so that they will not be conscious of the nature of the images (Penton-Voak et al., 1999). In particular, DeBruine (2004) showed facial images thus generated to 53 male and 55 female participants and asked them to evaluate the attractiveness of the faces. Participants were divided into same-sex, same-phenotypic-category (East Asian, European, or West Asian) groups, and each participant performed pairwise comparisons of faces resembling the members of the same group, including her or himself. When evaluating images of the same sex as the participants, both males and females found self-resembling faces more attractive than other group members judged them. In contrast, when evaluating opposite-sex images, neither males nor females found self-resembling faces significantly more attractive than other group members judged them. In other words, self-resemblance enhanced the attractiveness of same-sex faces but not that of opposite-sex faces.

However, an obvious question is: what does the word 'attractiveness' exactly mean when it is applied to same-sex or opposite-sex faces? More to the point, did DeBruine's participants use the same criteria when evaluating same-sex and opposite-sex faces? Besides, the finding that self-resemblance is irrelevant to the attractiveness of opposite-sex faces does not seem congruent with the observed facial resemblance between spouses. In a follow-up study, DeBruine (2005) approached these issues. In an experimental framework nearly identical to that of the previous study, 66 male and 78 female participants made pairwise comparisons of opposite-sex facial images resembling either themselves or other participants. They were asked to evaluate the faces based on three criteria: trustworthiness, attractiveness for a long-term relationship (e.g., marriage), and attractiveness for a short-term relationship (e.g., a 'one-night stand'). The results of the experiment suggested that self-resemblance enhances trustworthiness but represses attractiveness as a short-term partner of opposite-sex faces. Regarding attractiveness for a long-term relationship, facial resemblance did not have any significant effect.

A possible interpretation of these results is that a preference for self-resemblance is context dependent: people may tend to find, perhaps unconsciously, someone who is facially similar to themselves more desirable in social contexts, whereas they tend to find an opposite-sex individual resembling themselves less desirable in sexual contexts. It has been argued that a preference for self-resemblance in social contexts accords with inclusive fitness theory (Hamilton, 1964), which predicts that animals behave favorably toward close kin (DeBruine, 2002; Krupp et al., 2008). It has also been suggested that a preference against self-resemblance in sexual contexts may be an adaptation to avoid inbreeding (DeBruine et al., 2011). Since 'attractiveness' of an opposite-sex face is likely to involve both social and sexual contexts, it may be perceived on the basis of a balance between the two opposing effects of self-resemblance. This balance is unlikely to be constant across situations, which might partially explain the observed variation in the results of recent experiments (Lass-Hannemann et al., 2010; Kocsor et al., 2011; Nojo et al., 2011; Watkins et al., 2011).

Conclusion

We have reviewed some of the recent research on human mate choice driven by individuals' preference. We first looked at the interaction between genes and mate choice in humans and then explored two examples of physical traits on which human mate choice may depend: the MHC and facial characteristics. A number of researchers have contributed to this field to improve our understanding of the nature of human mate choice. Nevertheless, our current knowledge of the phenomenon is far from sufficient and further investigation is clearly needed.

Abstract

Evolutionary perspectives on human mating have generated a substantial corpus of work that reveals important sex differences in mate choice and preferences. Both men and women engage in multiple mating strategies, from long-term committed relationships to short-term sexual liaisons. This article summarizes how sex-specific adaptive problems faced by our ancestors shaped men's mate choices, including preferences for cues to fertility, sexual availability, faithfulness, and numerous partners; and women's mate choices, including preferences for cues to ambition, dependability, and investment potential. We also examine how these preferences differ in long-term compared to short-term mating contexts. Understanding the evolved nature of these differences is crucial not only in expanding understanding of human mating behaviors, but also in understanding the sexual conflict that results from sex differences in mate choice.

There are robust sex differences in men's and women's preferences for a romantic partner as a result of differences in mating-related adaptive problems recurrently faced by men and women over human evolutionary history. Mate choice also differs as a function of the type of relationship men and women are seeking. Using the lens of sexual strategies theory (Buss and Schmitt, 1993), this article highlights how men's and women's mate choice preferences help them solve sex-specific and temporal-specific mating-related adaptive problems.

Mating Strategies

Humans use a complex set of mating strategies. One of these strategies is long-term mating, which typically involves heavy commitment, pair-bonding, investment by both parents in offspring, and a reported feeling of being in love (e.g., Buss, 2003; Symons, 1979; Trivers, 1972). At the other end of the mating spectrum is short-term mating, which typically involves much less commitment and investment and places a greater emphasis on sexual behavior than long-term mating (e.g., Buss and Schmitt, 1993; Buss, 2003). Men and women can both employ a combination of mating strategies; that is, they can alternate between long-term and short-term mating or use some intermediate mating strategy. They may also use a dual mating strategy of maintaining a long-term relationship while seeking extra-pair copulations (Buss and Schmitt, 1993; Gangestad and Simpson, 2000; Schmitt et al., 2001a; Schmitt, 2005).

The frequency at which men and women employ each strategy differs partly as a function of their minimum obligatory parental investment. At a minimum women must bear the costs of gestation and lactation, whereas at a minimum men need only to contribute sperm and a few moments of their time (Trivers, 1972). The greater minimum obligatory parental investment women bear should cause them to be selective in their mating habits. The high metabolic costs of gestation and lactation and the decreased survival odds for children raised by a single mother (Daly and Wilson, 1988; Geary, 2007; Hewlett, 1988; Hill and Hurtado, 1996; Hrdy, 2007) further suggest women benefit by allocating more effort to a long-term relationship with an investing partner than to many casual relationships. Additionally, once a woman is pregnant she cannot become more pregnant by having sex with additional men, further suggesting the direct reproductive benefits to women of mating with multiple men are minimal. Alternatively, men's minimum parental obligation indicates they can be less selective in their mating habits, at least in short-term or polygynous mating contexts. Inseminating one woman does not necessarily prevent a man from inseminating additional women, suggesting the reproductive benefit to men of mating with multiple women is large (Trivers, 1972). Stated differently, for men a major constraint on their reproductive success historically has been sexual access to fertile women. Men and women historically have faced different mating-related adaptive problems as a result of these and other key differences in their reproductive biology, including internal female fertilization, lactation, and sharper age-graded fertility for women compared to men. These adaptive problems and how men and women solve them will be discussed below.

Men's Mating Strategies and Mate Choice

Short-Term Mating

As a result of men's minimum parental obligation, one effective method for men to increase their reproductive success is to increase the number of their sexual partners (Buss and Schmitt, 1993; Symons, 1979), suggesting they may benefit more from adopting a short-term mating strategy than a long-term strategy. For example, a man who already had one child could double his reproductive success by engaging in an additional short-term mateship resulting in pregnancy and successful childbirth, all else equal. Previous research suggests historically it was not the amount of times a man impregnated one woman that increased his reproductive success but instead it was the number of women he impregnated that mattered (see Betzig, 1988 for review).

Therefore one adaptive problem ancestral men would have to solve in order to increase their reproductive success would be the problem of partner number (Symons, 1979). One way to solve this would be to have sexual desire for a large number of

 http://dx.doi.org/10.1016/B978-0-08-097086-8.81049-1

sexual partners. Over ancestral history those men with this desire would theoretically have had more sexual partners, increasing their reproductive success more than men who did not possess this desire, suggesting men may have evolved a preference for sexual variety (Symons, 1979). In support of this, men report wanting to have a greater number of sexual partners than women across various time periods from the next month to the rest of their lifetime (Buss and Schmitt, 1993; Schmitt et al., 2001b; 2003; Simpson and Gangestad, 1991). Men also report having sexual fantasies about a greater number of sexual partners than do women (Ellis and Symons, 1990). Additionally men can solve the adaptive problem of acquiring multiple sexual partners by relaxing their standards – lower standards increase the chances they will find a partner (Buss and Schmitt, 1993). Kenrick et al. (1990) asked men to report their minimum acceptable threshold for a sexual partner, a date, and a marriage partner. Men reported lower standards for sexual partners than for dates or marriage partners on qualities, such as intelligence (Kenrick et al., 1990). Men also report lower standards for sexual partners or one-night stands than do women (Buss and Schmitt, 1993; Greitemeyer, 2005; Kenrick et al., 1990, 1993; Li and Kenrick, 2006; Regan, 1998a,b; Schieb, 2001: Schützwohl et al., 2009). Along with lowering their standards for a sexual partner, men can increase the numbers of partners they have by decreasing the amount of time they wait to engage in sexual intercourse with a new partner (Buss and Schmitt, 1993). When asked how long they would have to know someone before having sex, men were more willing to have sex after less time elapsed than were women (Buss and Schmitt, 1993; Schmitt et al., 2001c, 2003). Sexual attraction to a partner more quickly develops in men than in women (Clark and Hatfield, 1989; Clark et al., 1999; Hald and Høgh-Olesen, 2010; Rubin et al., 1981) and men frequently misperceive women's friendliness as a signal of sexual interest (Abbey, 1982; Haselton, 2003; Haselton and Buss, 2000; Perilloux et al., in press).

Not only did ancestral men have to solve the problem of partner number, but they also needed to determine which women were available to mate with and which of those women were fertile. Those men who spent time trying to mate with women who were not sexually accessible would produce less offspring than men who selected mates who were sexually accessible. Similarly, men trying to mate with women who were unable to conceive, such as those already pregnant, lactating, prepubescent, or menopausal would have left fewer offspring than men who selected fertile partners (Symons, 1979). This suggests men have evolved mate preference mechanisms that have two primary functions: select women who are available and displaying cues to fertility (Buss and Schmitt, 1993; Singh, 1993; see Buss, 2003 for review). Men value promiscuity and devalue prudishness and sexual inexperience in potential short-term partners, suggesting a preference for sexually accessible women (Buss and Schmitt, 1993; Oliver and Sedikides, 1992; Schmitt et al., 2001a). Additionally, evidence indicates men prefer women who are younger than they are and the age gap in preferences and actual mate selections tends to increase with men's age (Buss, 1989; Buunk et al., 2001; Greenlees and McGrew, 1994; Kenrick and Keefe, 1992). Youth in women is an indication of future reproductive potential, that is the potential for having a larger number of children in the future (Buss, 2003; Symons, 1979).

Men's psychological mechanisms recurrently used estrogen-dependent physiological cues to successfully estimate the age and hence reproductive value of prospective partners. Age-related cues include feminine facial and vocal qualities, smooth and clear skin, full lips, thick full hair, firm and symmetrical breasts, and small waists relative to the size of hips (Feinberg et al., 2006; Fink et al., 2001; Marlowe, 1998; Singh, 1993, 1995, 2002; Thornhill and Gangestad, 2008; Thornhill and Grammar, 1999). Women possessing these traits are perceived to be physically attractive, are highly desired as potential mates by men, and have high levels of estrogen and progesterone, which both increase conception likelihood (Jasienska et al., 2004; Singh, 2002; see Sugiyama, 2005 for review).

To be successful at mating with multiple partners, men also need to avoid getting entangled in a committed relationship and having to provide investment (Buss, 2003; Buss and Schmitt, 1993; Symons, 1979). Mating with a woman who required a large amount of investment or time from a man would decrease his opportunities to mate with other women. One way men can solve this problem is to prefer women who will not require a relationship or investment. Men perceive a commitment with a short-term partner as undesirable in comparison to a commitment with a long-term partner (Buss and Schmitt, 1993). Another way men can solve the problem of avoiding commitment is to experience a negative affective shift after sexual intercourse (Haselton and Buss, 2001). Men who pursue a short-term mating strategy rate first sexual encounters as better than later ones, lose interest in partners after a few days, weeks, or months, and decrease their perceptions of a partner's physical attractiveness after having sexual intercourse with her, and this perception continues to decrease further with time (Haselton and Buss, 2001). Ancestrally men who experienced a negative affective shift after sexual intercourse could more quickly detach from a potential long-term relationship than men who did not experience such a shift, providing those men with more time to acquire multiple mates.

Long-Term Mating

Although these findings suggest ancestrally men could best increase their reproductive success by employing a short-term mating strategy, men could also benefit by employing a long-term mating strategy. Seeking out multiple mates can take time and energy away from actual mating. Men can save that time and energy by staying with one long-term partner (Buss, 2003). Men who engage in short-term mating can never be certain that any offspring produced are theirs because they cannot be certain they have sole reproductive access to any of their partners. To solve this problem of paternity uncertainty, men can maintain a long-term relationship that provides them exclusive reproductive access to a woman (Alexander and Noonan, 1979; Buss and Schmitt, 1993; Thornhill and Gangestad, 2008), particularly if they employ mate guarding tactics to prevent insemination from other men (Buss, 1988a; Buss et al., 1992; Buss and Shackelford, 1997; Daly et al.,

1982; Shackelford et al., 2005a). Additionally, because high-quality women are highly desired by men, they can be choosier and demand more time and investment from men before they engage in sexual intercourse (Buss, 2003; Buss and Shackelford, 2008; Symons, 1979). By being willing to enter a long-term relationship, men may be able to obtain women of higher quality than if they attempt multiple short-term matings (Buss and Schmitt, 1993; Gangestad and Simpson, 1990; Symons, 1979; Thornhill and Gangestad, 2008). Although men might produce fewer offspring by not having multiple partners, they could still increase their reproductive success by producing high-quality offspring who would not only be likely to survive but who eventually would be highly sought after as mates. Additionally, regardless of offspring quality, the survival rate of offspring is increased when investment is provided by both parents (Daly and Wilson, 1988; Geary, 2007; Hewlett, 1988; Hill and Hurtado, 1996; Hrdy, 2007).

Evidence shows that men do engage in long-term mating. When asked how much they are currently seeking a long-term mate, men do not differ from women in their desire to find a long-term mate (Buss and Schmitt, 1993; but see Schmitt et al., 2001b for sex difference). Men place a greater emphasis on faithfulness and chastity in a long-term mate than in a short-term mate (Buss, 1989; Buss and Barnes, 1986; Buss and Schmitt, 1993; Buss et al., 2001). Furthermore, men view promiscuous behavior in potential long-term mates as undesirable (Buss and Schmitt, 1993). A preference for long-term mates possessing these traits helped ancestral men solve the adaptive problem of paternity uncertainty because faithful and chaste women would be less likely to be promiscuous (see Buss, 2003 for review).

Ancestrally, attempting to solely pursue short-term mating would have been a high-risk strategy for men. Given that highly desirable women can successfully demand large investment (Buss and Shackelford, 2008), and that women in general prefer long-term relationships (see below), men who attempted to only engage in short-term mating risked being shut out of the mating game entirely (Buss and Schmitt, 1993; Buss, 2003; Schmitt, 2005). It is more likely ancestral men pursued some combination of serial long-term relationships with occasional opportunistic short-term mating or extra-pair copulations, especially those men high enough in status or with enough resources to cross the polygyny threshold (Andersson, 1994; Daly and Wilson, 1983; Gangestad, 1993; Marlowe, 2000; Schmitt, 2005). This has changed drastically in the modern first-world environment – the anonymity of modern society makes it easier for men to deceive women into brief casual sexual liaisons at low costs to the men (Carroll et al., 1985; Garcia and Reiber, 2008; Paul and Hayes, 2002; Paul et al., 2000; Reiber and Garcia, 2010; Uecker and Regnerus, 2010). This is because the modern environment parasitizes men's evolved mating mechanisms, which gives the impression adopting a short-term mating strategy is universally the most beneficial mating strategy for men (see Jonason et al., 2009 as an example of this fallacy). However, men are not equally successful at short-term mating. Men possessing characteristics deemed highly valuable to women seeking short-term mates (see below) are considerably more successful than men who do not possess those characteristics (Jackson and Kirkpatrick, 2007; Landolt et al., 1995; Li and Kenrick, 2006). These findings indicate that men can rely on a suite of mating strategies to increase their reproductive success, and that men's mate preferences shift as a function of the type of strategy currently being executed.

Of course, these mating strategies are all enacted within different cultural contexts that sometimes constrain and sometimes enable one mating strategy over another (e.g., Gangestad et al., 2006). In cultures that cloister, veil, or guard women, for example, opportunities for short-term mating are severely restricted. In more sexually permissive cultures and in large cities that offer greater anonymity, short-term mating strategies are easier to implement.

Women's Mating Strategies and Mate Choice

Long-Term Mating

Women have a greater minimum obligatory parental investment than men, making them more selective in their mating decisions (Trivers, 1972). In traditional societies, which best resemble those of our ancestors, women spend much of their adult life either pregnant or lactating, and therefore are limited in the number of offspring they can produce (Sugiyama, 2005). Ancestrally, the most effective way for most women to increase their reproductive success was to heavily invest in each offspring produced to insure offspring lived until reproductive age. Paternal investment would have increased the likelihood of offspring survival and future success on the mating market (Geary, 2007; Hewlett, 1988; Hill and Hurtado, 1996; Hrdy, 2007). Therefore, ancestral women who were better at selecting and obtaining mates who were willing and able to invest in their offspring were more likely to leave surviving offspring than women who did not select, or could not obtain, investing partners (Buss, 1989, 2003; Buss and Schmitt, 1993; Schmitt, 2005; Symons, 1979).

Women's mating mechanisms, therefore, must solve the adaptive problem of determining investment ability in potential partners. Ancestrally, women could have ascertained this by a man's potential for accruing resources, which in the modern environment equates with monetary resources (Symons, 1979; Buss, 2003). Ancestral men with the ability to accrue resources were better able to provide tangible investment, such as shelter and food, than could men who lacked this ability. Women who selected men who could accrue resources as partners would have produced more offspring who survived than women who chose other men. In modern environments, women consistently rate qualities synonymous with economic resources, such as good earning capacity, wealth, good financial prospects, and a reliable future career, as more important for a potential long-term mate to possess than do men (e.g., Bereczkei et al., 1997; Buss, 1989; Buss and Barnes, 1986; Buss and Schmitt, 1993; Buss et al., 2001; Greenlees and McGrew, 1994; Kenrick et al., 1993, 1990; Pawlowski and Dunbar, 1999; Sprecher et al., 1994; Waynforth and Dunbar, 1995). Ambition is correlated with the drive and ability to acquire resources, and women prefer long-term partners who are ambitious (e.g., Buss, 1989; Buss and Barnes, 1986; Buss et al., 2001; Kenrick et al., 1993, 1990) and will even prefer

ambitious yet physically unattractive men to nonambitious yet physically attractive men (Sritharan et al., 2010; Townsend and Wasserman, 1998; Wilbur and Campbell, 2010). Another way women can determine a man's potential to acquire economic resources is to evaluate his social status. Men with higher social status tend to accrue greater resources than do men with lower social status. Women prefer long-term mates with high social status (e.g., Buss, 1989; Kenrick et al., 1993, 1990; Li et al., 2002; Rajecki et al., 1991; Townsend and Levy, 1990 a,b). Additionally, women tend to rate men low in these qualities as undesirable as a long-term mate (Buss and Schmitt, 1993).

Just determining a man's investment ability would not have been enough for ancestral women to insure offspring survivability. They also had to solve the adaptive problem of determining if the man would be willing to invest his resources and time specifically in her and any potential offspring. It would not help offspring survival if a man had plentiful resources but spread them among many women or diverted them to another woman's offspring (Buss et al., 1992; Symons, 1979). One marker of this willingness is a man's commitment to the relationship, which can be determined by cues of fidelity and love (Buss, 2003). In one study, women rated acts of resource display, such as 'surprised her with a gift' and 'bought a special present for her' as indicative of a man being in love. Also rated highly were acts indicative of fidelity, such as 'remained faithful when they were separated for more than a month' and 'gave up going out with other women for her' (Buss, 1988b). Similarly men interested in keeping a mate frequently use resource display and commitment-increase retention tactics (Buss, 1988a; Buss and Shackelford, 1997; Shackelford et al., 2005). These behaviors indicate a man is willing to commit his resources and time to one woman and their joint offspring, increasing the chances offspring will receive necessary investment to survive.

The odds that offspring would have survived ancestrally also could have been increased by selecting long-term mates who provided not just resources, but who also displayed characteristics indicative of being a good parent and being willing to help raise offspring. Offspring raised by both biological parents have an increased likelihood of surviving than do offspring raised by one parent (Daly and Wilson, 1988; Geary, 2007; Hewlett, 1988; Hill and Hurtado, 1996; Hrdy, 2007). Cues indicating potential good parenting skills include dependability and emotional stability, kindness and sincerity, and similar personalities, interests and backgrounds (see Buss, 2003 for review). Women consistently rate these characteristics as important for potential long-term mates to possess. Kindness, dependability, and emotional stability often rank at the top of women's list of required preferences for a long-term partner (Buss, 1989; Buss and Barnes, 1986; Buss et al., 2001; Evans and Brase, 2007; Fletcher et al., 2004; Kenrick et al., 1993, 1990; Li et al., 2002; Regan, 1988a; Scheib, 2001). Women can assess a man's ability to be a good parent by observing his interactions with children. Interacting with children increases women's perceptions of a man's attractiveness in comparison to perceptions of his attractiveness when he is alone (Brase, 2006; La Cerra, 1995). Additionally, women appear to be able to detect men's interest in infants simply by viewing images of men's faces. Women rate men expressing greater interest in infants as more attractive potential long-term mates than men who do not show such interest (Roney et al., 2006). Women whose psychological mechanisms led them to select men possessing these traits and with an interest in children would have had more help raising offspring, increasing offspring survivability, and ultimately the women's own reproductive success, than would women whose psychological mechanisms led them to select other men as partners. Although long-term mating is extremely beneficial to women, there are contexts in which women can also benefit from engaging in short-term mating.

Short-Term Mating

Pregnancy and lactation require large amounts of investment and resources but parental investment can have diminishing returns (Cashdan, 1993; Low, 1990). Therefore if women can obtain their own resources, they do not necessarily stand to benefit from obtaining *more* resources from a potential mate. Ancestrally women may have obtained their own resources through their family and could therefore afford to trade-off requiring investment from potential partners for other noninvestment qualities (Gangestad, 1993). In these cases, women would actually benefit by shifting toward a more short-term mating strategy (Gangestad and Simpson, 2000) because men of high presumptive genetic quality often choose to focus more effort on short-term mateships rather than long-term mateships (Apicella and Marlowe, 2007; Buss, 2003; Marlowe, 1999; in birds: Møller and Thornhill, 1998; Rhodes et al., 2005; Schmitt, 2005; Thornhill and Gangestad, 2008). Ancestrally women could have also obtained resources by having a long-term committed partner. When this occurred, women may have chosen to risk the certain investment from their long-term partner by engaging in extra-pair copulations with men of high presumptive genetic quality (Buss, 2003; Gangestad and Simpson, 2000; Greiling and Buss, 2000; Thornhill and Gangestad, 2008). What this suggests is women may have evolved adaptations for employing either a short-term mating strategy or a dual mating strategy, but these adaptations evolved to solve different mating-related adaptive problems than did men's (Buss, 2003; Buss and Schmitt, 1993; Gangestad and Simpson, 2000; Greiling and Buss, 2000; Schmitt et al., 2001a; Schmitt, 2005; Thornhill and Gangestad, 2008).

Unlike for men, there is no direct or linear increase to a woman's reproductive success by having sexual intercourse with multiple partners. Instead, women can increase their reproductive success, in principle, by having sexual intercourse with men possessing 'good genes' (e.g., Gangestad and Simpson, 2000; Greiling and Buss, 2000; Simpson and Gangestad, 1991; Thornhill and Gangestad, 2008; Trivers, 1972). Good genes are currently thought to be those indicative of good health and increased chances of survivability (see Andersson, 1994 for review). Mating with a man possessing good genes therefore increases chances for offspring survival. Additionally, because women who employ a short-term mating strategy tend to prefer men who advertise their good genes, mating with a man who possesses good genes should increase the chances a woman's male offspring will be able to find a mate and produce offspring, thereby increasing her

reproductive success ('sexy sons' hypothesis; Buss, 2003; Fisher, 1930; Kokko et al., 2002; Smith, 1984; Thornhill and Gangestad, 2008).

If women recurrently engaged in short-term mating to obtain partners with 'good genes,' then their psychological mechanisms should have evolved to solve the adaptive problem of detecting genetic quality of potential partners (Thornhill and Gangestad, 2008). Ancestral women who selected partners with good genetic quality would have been more likely to produce offspring with increased survival odds than women who selected partners with decreased genetic quality.

Women obviously cannot detect underlying genetic quality in a potential mate, but instead can use statistically correlated phenotypic markers of good genes. One such set of phenotypic markers are those indicating masculinity (Frederick and Haselton, 2007; Penton-Voak et al., 1999; Thornhill and Gangestad, 1993, 1999). Masculinity is positively correlated with body symmetry, and a high degree of body symmetry indicates low amounts of developmental instability. Developmental instability is a measure of ability to overcome exposure to prenatal pathogens and mutations. Therefore, men with low levels of developmental instability can be considered to have higher fitness and better genes than men with greater amounts of developmental instability (Gangestad and Simpson, 2000; Gangestad and Thornhill, 1997; Gangestad et al., 1994; Thornhill and Gangestad, 1999, 2008). Women interested in short-term mating rate men displaying characteristics perceived as masculine as more attractive than those appearing more feminine (Gangestad, 1993; Johnston et al., 2001; Penton-Voak et al., 2003, 1999) and prefer to short-term mate with men considered attractive (Buss and Schmitt, 1993; Greiling and Buss, 2000; Kenrick et al., 1993; Li and Kenrick, 2006; Rhodes et al., 2005; Simpson and Gangestad, 1992; Wiederman and Dubois, 1998; Wilbur and Campbell, 2010). These findings suggest women have evolved psychological mechanisms functioning to select short-term partners with high genetic quality.

Women may not engage in short-term mating solely to obtain good genes for their offspring. Instead, given the great importance of long-term relationships to women, they may engage in short-term mating to assess a man as a potential long-term partner (Buss and Schmitt, 1993; Buss, 2003; Greiling and Buss, 2000; Shackelford et al., 2004). Choosing a poor long-term partner would have been extremely costly to ancestral women, especially in exogamous societies, which would have left women without physically close familial support (Buss, 2003; Buss and Schmitt, 1993). Women who used short-term mating to assess potential partners for long-term relationships, and were able to correctly determine which ones would make a good long-term partner, would have had greater reproductive success than those women who could not make such determinations (Buss, 2003; Buss and Schmitt, 1993). Women should, therefore, have evolved psychological mechanisms to solve the adaptive problem of partner assessment.

Women can solve the problem of partner assessment by selecting short-term partners with similar characteristics to highly preferred long-term partners (Buss and Schmitt, 1993). When considering potential short-term partners, women consider a man's financial resources and generosity important (Wiederman and Dubois, 1998) – two traits women seeking long-term partners also consider important (Buss, 1989; Buss and Barnes, 1986; Buss et al., 2001; Kenrick et al., 1993, 1990; Li et al., 2002; Scheib, 2001). In general, women's preferences for potential short-term partners are as stringent as their preferences for a long-term mate, suggesting they may use short-term mating as an assessment strategy (Buss and Schmitt, 1993; Li and Kenrick, 2006; Kenrick et al., 1993, 1990; Regan, 1998a,b; Shackelford et al., 2004; Sprecher and Regan, 2002; Surbey and Conohan, 2000). The assessment problem can also be solved by specifically decreasing preferences for traits in short-term partners that are detrimental to quality if present in a long-term partner. For example, women should not want a promiscuous long-term partner due to the risk of costly investment loss, and if using short-term mating as an assessment tool, should also express a decreased interested in promiscuous men as short-term partners (Buss, 2003; Buss and Schmitt, 1993; Schmitt et al., 2001b). Women seeking a short-term partner rate promiscuity as undesirable in their potential mates (Buss and Schmitt, 1993; Schmitt et al., 2001b; Wiederman and Dubois, 1998). Additionally if women use short-term mating as an assessment strategy for a long-term relationship, they should experience an affective shift after having sexual intercourse with men who would be good long-term partners to promote the formation of a long-term pair bond (Haselton and Buss, 2001). These findings suggest women do engage in short-term mating to assess men as potential long-term partners, although men too might use short-term mating to gauge long-term quality.

Women may also engage in short-term mating to acquire immediate resources instead of the promise of future resource investment they seek in long-term partners. Ancestral women may have needed immediate resources, such as scarce game meat to help provision offspring, and could have acquired such highly valued resources by exchanging them for sex (Buss, 2003). For example, better hunters in the Aché (a traditional hunter-gatherer society) have more mistresses and those mistresses report having more illegitimate children by the more skilled hunters (Hill and Hurtado, 1996; Hill and Kaplan, 1988). If acquiring resources sooner rather than later helped women survive or produce more viable offspring, then women should have evolved psychological mechanisms for preferring as short-term partners men who are willing to provide immediate resources (Buss, 2003; Buss and Schmitt, 1993; Symons, 1979). Buss and Schmitt (1993) asked women to rate four behaviors related to early resource provisioning: 'spends a lot of money on me early on,' 'gives me gifts early on,' 'has an extravagant lifestyle,' and 'stingy early on.' Women valued the first three behaviors for potential short-term partners more than for long-term partners, but devalued the last behavior for potential short-term partners (Buss and Schmitt, 1993). Other research has corroborated these findings – when seeking a short-term partner women place a premium on immediate resource investment (Bereczkei et al., 1997; Fletcher et al., 2004; Kenrick et al., 1990, 1993; Regan, 1998 a,b; Townsend and Levy, 1990a,b). The strong demonstrated preference women seeking short-term partners have for immediate investment

suggests women do use short-term mating as an opportunity to obtain immediate material benefits for themselves or any current offspring.

Although long-term mating is often a more beneficial strategy to women's reproductive success than short-term mating, evidence suggests women do at times engage in short-term mating. Statistically speaking, every time a man has sex with a new partner, a woman is also having sex with a new partner. This suggests the mean number of sex partners for men and women must be identical, assuming an equal sex ratio in the mating pool (Buss, 2003; Greiling and Buss, 2000). Similarly, men's strong desire for sexual variety could not have evolved if ancestral men never obtained access to multiple sexual partners (Schmitt et al., 2001b; Schmitt et al., 2001c; Schmitt et al., 2003; Smith, 1984), suggesting that at least some ancestral women were willing to engage in brief sexual encounters with multiple men. In recent studies on hook-up behavior, between 50 and 75% of college women report engaging in at least one casual sexual encounter within the last year, and these numbers closely parallel college men's reports of their own casual sex behavior (Garcia and Reiber, 2008; Grello et al., 2006; Paul and Hayes, 2002; Paul et al., 2000; Reiber and Garcia, 2010; Uecker and Regnerus, 2010).

Additional support for women having an evolved short-term mating psychology comes from men's physiology. As a function of the risk of sperm competition, species' testes size is correlated with the species' specific mating strategies. Sperm competition occurs when the sperm of two or more males occupy a female's reproductive tract simultaneously (Baker and Bellis, 1993 a,b; Parker, 1970; Smith, 1984). More monogamous primate species face less risk of sperm competition and therefore have smaller testes relative to body size than do polygamous primate species. For example, male gorillas have sole reproductive access to a harem of female gorillas and their testes size is less than 0.1% of their total body weight, whereas male chimpanzees compete for access to fertile females and their testes are about 0.3% of their weight. Human male testes size falls in the middle of these two species, suggesting humans are not entirely monogamous such as the gorillas, or entirely promiscuous such as the chimpanzees (see Pound et al., 2006; Shackelford et al., 2005b, c for review). If human females did not engage in short-term mating, there would be no selection pressure on males' physiology to cope with the threat of sperm competition, and human testes would be proportionally similar to the testes of gorillas. However, because human testes are not proportionally similar to gorilla testes, it is reasonable to infer that across evolutionary history, human males did have to solve the adaptive problem of sperm competition some of the time, providing evidence for females occasionally employing some form of a short-term mating strategy. As with men, it is clear women rely on a suite of strategies and their mate preferences shift accordingly to match the current strategy being executed.

Conclusion

As a result of differences in minimum obligatory parental investment, men and women differ in how they can best increase their reproductive success. When possible, men's reproductive success historically was best be increased through low-cost opportunistic mating or polygynous mating, whereas women's reproductive success is best increased through high-quality long-term investment mating. Although men and women both employ a variety of mating strategies, their preferences when pursuing these strategies fundamentally differ. One consequence of these sex differences is sexual conflict, jealousy, sexual aggression, sexual harassment, and rape are often products of differences in men's and women's mate preferences and desires. Understanding the evolved nature of men's and women's mate choice contributes to our understanding of these darker elements of human mating in addition to our broader understanding of mating psychology.

Abstract

Human resource management (HRM) includes five broad activities that together constitute the HRM system: staffing, retention, development, adjustment, and managing change. Its objectives are to optimize the performance and productivity of all workers in an organization, and to help line managers manage those workers more effectively. Modern HRM traces its roots to a variety of historical influences, beginning with the industrial revolution. New challenges face today's HR managers based on the new paradigm of work: anytime, anywhere, in real space or in cyberspace.

At a broad level, human resource management (HRM) is concerned with choices – choices that organizations make from a wide variety of possible policies, practices, and structures for managing employees. Managing employees effectively has important consequences for individuals themselves as well as for the organizations that employ them. Thus there exists a substantial and growing body of research evidence showing a strong connection between how firms manage their people and the economic results they achieve (Crook et al., 2011).

As practiced in work organizations, HRM includes five broad activities that together constitute the HRM system: staffing, retention, development, adjustment, and managing change (Cascio, 2013). These activities can be carried out at the individual, work team, or larger organizational unit (e.g., department) level. They are the responsibility of every line manager, as well as of the HRM department.

Staffing comprises the activities of (1) identifying work requirements within an organization, (2) determining the numbers of people and the skills mix necessary to do the work, and (3) recruiting, selecting, and promoting qualified candidates. *Retention* comprises the activities of (1) rewarding employees for performing their jobs effectively, (2) ensuring harmonious working relations between employees and managers, and (3) maintaining a safe, healthy work environment. *Development* is a function whose objective is to preserve and enhance employees' competence in their jobs by improving their knowledge, skills, abilities, and other characteristics; HR specialists use the term 'competencies' to refer to these items. *Adjustment* comprises activities intended to maintain compliance with the organization's HR policies (e.g., compensation and discipline) and business strategies (e.g., innovation and cost leadership). *Managing change* is an ongoing process whose objective is to enhance an organization's ability to anticipate and respond to developments in its external and internal environments, and to enable employees at all levels to cope with the changes. As Jack Welch, legendary former CEO of General Electric, noted, "Look, HR should be every company's 'killer app.' What could possibly be more important than who gets hired, developed, promoted, or moved out the door? Business is a game, and as with all games, the team that puts the best people on the field and gets them playing together wins. It's that simple" (Welch and Welch, 2006, p. 92).

Responsibilities and Objectives

HRM activities can be carried out at the individual, work team, or larger organizational unit (e.g., department) level. Sometimes they are initiated by the organization (e.g., recruitment efforts or management development programs), and sometimes they are initiated by the individual or work team (e.g., voluntary retirement or safety improvements). It might appear that the activities of staffing, retention, development, adjustment, and managing change are the special responsibilities of the HR department. However, these responsibilities also lie within the core of every manager's job throughout any organization – and because line managers have the authority (the organizationally granted right to influence the actions and behavior of the workers they manage), they have considerable impact on the ways that workers actually behave. This implies two things: (1) a broad objective of HRM is to optimize the performance and productivity of all workers in an organization and (2) a special objective of the HR department is to help line managers manage those workers more effectively. The HR department accomplishes this special objective through policy initiation and formulation, advice, service, and control in close communication and coordination with line managers.

Generally speaking, HR specialists provide the technical expertise in each area, while line managers (or, in some cases, self-directed work teams) use this expertise in order to manage people effectively. In a small business, however, line managers are responsible for both the technical and managerial aspects of HRM.

For example, to enhance retention, line managers are responsible for treating employees fairly, resolving conflicts, promoting teamwork, and providing pay increases based on merit. To help line managers do these things effectively, the HR department must devise a compensation and benefits system that employees will perceive as attractive and fair, establish merit increase guidelines that will apply across departments, and provide training and consultation to line managers on all employee relations issues, such as conflict resolution and team building.

The Evolution of Human Resource Management

To appreciate where the field is today, it is instructive to examine its historical roots. As it is practiced in most developed

countries around the world, modern HRM has emerged from nine interrelated sources.

1. Rapid technological change that increased the specialization of labor associated with the industrial revolution
2. The emergence of free collective bargaining, with constraints established for unions and for employers
3. The scientific management movement
4. Early industrial psychology
5. Governmental personnel practices growing out of the establishment of the United States Civil Service Commission
6. The emergence of personnel specialists and the grouping of these specialists into personnel departments
7. The human relations movement
8. The behavioral sciences
9. Social legislation and court decisions

The following sections describe each of these sources in more detail.

The Industrial Revolution

Three characteristics of the industrial revolution were the development of machinery, the linking of human power to the machines, and the establishment of factories in which a large number of people were employed. The result was a tremendous increase in job specialization as well as in the amount of goods that workers could produce. 'Division of labor' became a rallying cry of this revolution.

Clearly, the industrial revolution greatly accelerated the development of business and commerce. Owners and entrepreneurs generally did quite well for themselves, but the average citizen fared poorly in comparison to today's workers in terms of purchasing power and working conditions. Labor was considered a commodity to be bought and sold, and the prevailing political philosophy of *laissez-faire* resulted in little action by governments to protect the lot of workers. Twelve-hour workdays were common, tens of thousands of workers were killed on the job, wages were often below the level needed to support a family, job insecurity and unemployment were constant threats, and blatant discrimination and harsh treatment were everyday experiences. Against this backdrop, it was inevitable that workers would organize collectively to improve their wages and working conditions. Thus, an increasingly assertive and sometimes radical trade union movement grew (Kaufman, 2008).

The Emergence of Free Collective Bargaining

Because of the way they were abused, workers organized collectively to protect themselves and to improve their lot in life. From their perspective, the industrial revolution fostered specialization, along with the need for workers within each specialization to organize themselves against its abuses. Trade unions, also called 'labor unions,' spread rapidly, and so did the incidence of strikes (see also Labor Unions). The first overt union activity in the United States took place in 1794, when the Philadelphia shoemakers attempted to raise their wages in reaction to a wage cut by their employers. The employers sued the union, arguing that workers who jointly attempted to raise their wages constituted an illegal conspiracy in restraint of trade. In 1806, a federal court ruled in favor of the employers and fined the employees involved. Until this 'conspiracy doctrine' was overturned in 1842 in the case of *Commonwealth of Massachusetts v. Hunt*, workers were discouraged from forming unions. In the *Hunt* case, the court ruled that labor unions were not criminal per se, for they could have honorable as well as destructive objectives. In short, a union's conduct will determine whether it is legal or illegal (Commons and Filmore, 1958). Nevertheless, in the United States, courts generally adopted an antiunion stance until 1935. In that year, the National Labor Relations Act was passed. It focused largely on labor's right to organize. It became an unfair labor practice for an employer to coerce or restrain employees in the exercise of their rights, to dominate or interfere with a labor organization, or to refuse to bargain collectively with a legal representative of the employees. Subsequent legislation refined, broadened, and set legal limits on the scope of management and union activities. From the perspective of labor, the development of free collective bargaining and the USA labor movement created the need for what is now recognized as effective HRM.

Scientific Management

From the perspective of management, the scientific management movement also created the need for effective HRM in order to bring order and rationality to the practice of management. Frederick Winslow Taylor was the prophet of scientific management, and the stopwatch was his 'bible' (Bell, 1972). Taylor began his experiments in the steel industry in 1885. His objective was the systematic analysis of work, which he broke down into its smallest mechanical elements, and then rearranged into the most efficient combination. The objective was to identify the 'one best way' to perform work. In addition to the scientific study of the task itself ('time and motion' study), Taylor argued that the individuals selected to do the work should be as perfectly matched physically and mentally to the demands of the job as possible, and that overqualified individuals should be excluded.

Employees should be trained carefully by supervisors (whose own work was also divided into specialties) to ensure that they perform the work exactly as specified by prior scientific analysis. In no case, however, should employees ever be called upon to work at a pace that would be detrimental to their health.

Finally, to provide an incentive for the employee to follow the detailed procedures specified (and closely supervised by line supervisors on the shop floor), Taylor felt that employees should receive an addition of between 30 and 100% of their ordinary wages when the task was done right and within the time limits specified. The first piece-rate incentive system had arrived.

Taylor also was interested in the social aspects of work, although he saw little good emerging from the social interaction within work groups. He felt that work groups fostered a level of individual efficiency equal to that of the least productive worker in the group. In other words, he believed that the efficiency of the group would not be any greater than that of its least productive member. Thus Taylor tried to institute a kind of social physics into the workplace.

Nevertheless, jobs designed only to maximize efficiency lead to predictable psychological consequences, and these have been well documented (Blauner, 1964; Kornhauser, 1965). Such jobs often lead to job dissatisfaction, surface attention to work, depersonalization, feelings of alienation (i.e., powerlessness and meaninglessness), and frustration due to lack of personal growth and development. In the context of automobile assembly line jobs in the early 1900s, Henry Ford lamented, "Why is it that I always get a whole person when what I really want is a willing pair of hands?" (quoted in Labich, 1994). On balance, however, while many of Taylor's ideas were controversial, there is no doubt that application of scientific management principles resulted in much higher productivity than would otherwise have been possible.

Early Industrial Psychology

The objective of early industrial psychology was to improve organizational goals (productivity and efficiency) primarily by applying psychology with an emphasis on individual differences through employee selection and training (Koppes, 2007). Hugo Munsterberg's 1913 book, *Psychology and Industrial Efficiency*, described experiments in selecting streetcar operators, ship's officers, and telephone switchboard operators. His contributions to human resource (or personnel) management are noteworthy for his emphasis on job analysis in terms of (1) the abilities required to do the job and (2) the development of testing devices – aptitude as well as work sample tests – that were able to forecast subsequent job performance (Munsterberg, 1913).

Munsterberg's 1917 book, *Business Psychology*, included the results of questionnaires sent to hundreds of laborers. The questionnaires requested anonymous data on attitudes toward their work, their involvement in the labor movement, and their leisure activities.

Both Munsterberg and Taylor were concerned with how workers were selected for jobs, as well as with the individual worker's feelings and aspirations. Although they differed on several issues (notably, on how social structure affected productivity), Munsterberg's writings clearly suggest that he felt that the two emerging fields of personnel selection and social psychology (the study of how people affect and are affected by one another) were complementary (Landy, 1992; Moskowitz, 1977).

When the United States entered World War I in 1917, psychologists Walter Dill Scott, Walter VanDyke Bingham, and Robert Yerkes collaborated in developing intelligence tests that could be used to select and classify recruits. The Army Alpha was administered to individuals with English-language skills, while the Army Beta was administered to recruits who were illiterate or did not have strong English-language skills. These tests paved the way for large-scale intelligence testing and for later expansion of psychological testing into government, industry, and education (Vinchur and Koppes, 2011).

Other developments at about the same time included the use of rating sheets for interviewers, advances in checking references given by workers, and advances in statistical methods for estimating validity (the extent to which selection devices accurately forecast job performance). Other kinds of psychological measures also appeared during and after World War I, such as measures of aptitude, interest, and personality. The measurement of attitudes was made possible by the scaling techniques of L. L. Thurstone in 1927, and improved further by Rensis Likert in 1932. Likert-type rating scales (e.g., scales with possible answers like *strongly agree*, *agree*, *neither agree nor disagree*, *disagree*, and *strongly disagree*) are still popular today.

The US Civil Service Commission

Employment in the federal government had reached 130 000 by the 1880s, and by 1920 it had surpassed 600 000, making it the nation's largest employer. Prior to civil service reform in 1883, federal employment was subject to the patronage, or 'spoils,' system. Government jobs were rewards that elected officeholders used to raise money and to reward their political supporters, based on the philosophy that "to the victor goes the spoils" (Kaufman, 2008). That system ended after a disappointed office seeker shot and killed President James Garfield in 1881, an event that galvanized public opinion against the spoils system. In its place, the Pendleton Act of 1883 established the US Civil Service Commission (today known as the US Office of Personnel Management). A forerunner in progressive personnel policies, the act provided that fair, open, and competitive examinations be administered to implement merit-based employment in the public service. It also provided a measure of employment security for those selected, prohibited discharge for refusing to engage in political activity, encouraged a nonpartisan approach to appointments, and mandated that a commissioner administers the act (Van Riper, 1958). Perhaps, the major impact of this act was to protect employment and promotion policies in the federal government from political influence. Over the years, these policies have influenced personnel practices in state and local governments as well as in private industry.

Private Industry's Approach to Personnel Management

Historians consider 1912 as the approximate date of the emergence of the modern personnel department (Eilbert, 1959). The term 'personnel,' with its connotation of managing people in organizations, began to appear around 1909. Between 1900 and 1920, while advances were being made in scientific management, industrial psychology, and the federal civil service, a number of personnel specialists or employment managers emerged in companies such as B. F. Goodrich, National Cash Register, and Standard Oil of California. The specialists managed such areas as employment, employee welfare (financial, housing, medical, and educational), wage setting, safety, training, and health. The employment management movement, born in Boston with the founding of the Employment Managers' Association of Boston in December 1912, was an early forerunner of the modern human resources department. Meyer Bloomfield, Louis Brandeis, and the Filene Brothers were key players in the development of this movement. It represented a newfound appreciation of the role of labor – the human factor – as a source of competitive advantage if it was managed wisely and humanely (Kaufman, 2008).

The Human Relations Movement

In Chicago in 1923, the Hawthorne Works of the Western Electric Company provided the setting for one of the most famous behavioral research efforts of all time. The purpose of the research was to study the effects of illumination (lighting) on worker productivity. In one experiment, production went up when the illumination increased. In another experiment, production went up when the illumination decreased. After three years of continually inconsistent results, the researchers concluded that in a situation involving people, it was impossible to change one condition (the lighting) without affecting other variables at the same time. Employee motivation and work group morale seemed to be the really crucial factors.

The results of subsequent experiments at the Hawthorne Works by Professors Elton Mayo, Fritz Roethlisberger, and T. North Whitehead of the Harvard Business School indicated that productivity was directly related to the degree of group teamwork and cooperation. The level of teamwork and cooperation, in turn, seemed to be related to the interest of the supervisor and the researchers in the work group, the lack of coercive approaches to productivity improvement, and the participation afforded the workers in changes affecting them (Pennock, 1930; Roethlisberger and Dickson, 1939). In short, the researchers came to view the organization of workers as a *social system*, in contrast to Taylor's view of that organization as a *technical–economic system*. Interest and research in topics such as leadership, motivation, group processes, and job satisfaction have direct antecedents in the Hawthorne research (Vinchur and Koppes, 2011).

The conviction that group behavior and workers' feelings were associated with morale and productivity characterized much of the research and theorizing in the human relations movement in the 1940s and the 1950s. Influential thinkers such as Douglas McGregor (Theory X and Theory Y managers), Chris Argyris (modern organizations are in conflict with the personalities of mature adults), and Rensis Likert (the 'linking pin' model of integrating small groups into the organization) focused on the fit between organizations and individuals. Their ideas can be summed up concisely: organizations and people need each other, and a good fit between the two benefits both (Shafritz and Ott, 1996).

In practice, unfortunately, many managers seemed to use human relations for the short-term purpose of manipulating workers to increase output, rather than for the long-term goal of satisfying worker needs while meeting organizational needs. Failure to find evidence that these programs made a difference in workers' satisfaction, or that happy workers were productive workers, helped kill this approach to HRM (Brayfield and Crockett, 1955).

The Behavioral Sciences

The behavioral-science approach to managing people is an outgrowth of human relations studies, although it embraces a wider base of academic and applied disciplines and is concerned with a wider range of problems. *Behavioral sciences* refer to the social and biological sciences concerned with the study of human behavior. Much of the knowledge of HRM and many of its practical applications have come from such behavioral-science disciplines as the following:

1. *Industrial/organizational psychology*: the study of the behavior of people at work (see Industrial-Organizational Psychology: Science and Practice)
2. *Social psychology*: the study of how people affect and are affected by one another
3. *Organization theory*: basic philosophies about why organizations exist, how they function, how they should be designed, and how they can be effective
4. *Organizational behavior*: the study of the causes of individual and group behavior, and of how this knowledge can be used to make people more productive and satisfied in organizational settings
5. *Sociology*: the study of society, social institutions, and social relationships

Another area that has exerted a considerable influence on HRM theory and practice is *general systems theory*. Systems theory has developed from such fields as biology, physics, and cybernetics (the study of mechanical–electrical communications systems and devices). It has been applied and elaborated in every behavioral science field.

We now know that the ways people behave in organizations cannot be explained simply by human relationships. The organization itself, through its unique 'culture,' molds, constrains, and modifies human performance. *Organizational cultue* has been described as the DNA of an organization – invisible to the naked eye, but critical in shaping the character of the workplace (Tetenbaum, 1999). *Culture* is the pattern of basic assumptions a given group has invented, discovered, or developed in learning to adapt to both its external and internal environments. This pattern of assumptions has worked well enough to be considered valid and, therefore, to be taught to new members as the correct way to perceive, think, and feel in relation to those problems (Martin, 2002; Schein, 2004). The way the organization is structured, the authority attached to different positions, and job and technology requirements clearly affect behavior, as do stories, legends, and myths about key people and events; what leaders pay attention to, measure, and control; and any implicit and possibly unconscious criteria that leaders use to determine who fits key slots in the organization (Schneider et al., 2011). Even though the present understanding of the determinants and effects of behavior is incomplete, there is a better sense of the ways in which separate influences interact with each other to affect individuals.

Social Legislation and Court Decisions

Governments in most developed countries around the world have passed social legislation, and courts have issued decisions on unfair discrimination in employment. While some countries are more aggressive in enforcing these issues than others, the laws and court decisions frame national policy on equal employment opportunity (EEO). In the United States, discrimination in employment is prohibited on the basis of race, religion, national origin, gender, age, and disability. Aggrieved individuals have the right to pursue their claims in court. At the organizational level, HRM professionals work with top

managers to develop and implement EEO policies to ensure that individuals are treated fairly in all aspects of the employment relationship.

Learning from the Past, Looking toward the Future

As noted earlier, the field of human resource management system is composed of five broad activities: staffing, retention, development, adjustment, and managing change. The field as it is known today has emerged from nine interrelated sources: the industrial revolution, the emergence of free collective bargaining, scientific management, early industrial psychology, governmental personnel practices growing out of the establishment of the US Civil Service Commission, the emergence of personnel specialists and the grouping of these specialists into personnel departments, the human relations movement, the behavioral sciences, and social legislation and court decisions.

Today's HR professionals need to be proactive, not reactive. They must anticipate changes in the social, legal, political, and economic environments, and then facilitate effective organizational responses to them. Some of these issues include finding and keeping top talent in tight labor markets, and capitalizing on the information revolution in ways that will benefit organizations, such as social media and other Internet-based recruitment sources. HR professionals must take the lead in establishing sensible privacy-protection policies for employees, and developing interactive, company-based intranets to facilitate employee inquiries and inputs. Other challenges include managing the performance of geographically dispersed employees and teams (virtual teams), and providing training and development opportunities on demand.

Many of the ways of working that we have taken for granted are disappearing – working nine to five, spending an entire career with only one company, taking weekends off, working with people we have known well, and working in offices we go to every day. Similar changes are happening in organizations. For example, the idea that hierarchy is the best way to manage information flows, that most people will work with team members in the same office, or that the majority of talent will be held within the boundaries of an organization. All of this is shifting, and what is coming in its place is less knowable and less understandable – accelerating technology, accelerating globalization, accelerating demographic changes, and accelerating social trends (Gratton, 2011).

Indeed, this is today's paradigm of work: anytime, anywhere, in real space or in cyberspace. This presents ongoing challenges in areas such as work-life fit (Galinsky and Matos, 2011); developing a total rewards package that will attract, retain, and motivate employees at all levels (Lawler, 2011); measuring social networks to identify trusted connections (Stephenson, 2011); promoting collective leadership (Boudreau and Ziskin, 2011); and promoting and enabling ambidextrous leadership that will identify new growth businesses, while remaining focused on the execution of existing ones (Probst et al., 2011). HRM will contribute to the bottom-line success of organizations and to the betterment of employee welfare by developing proactive responses to the workplace challenges wrought by this new paradigm.

Human Rights and Social Work

Elisabeth Reichert, Southern Illinois University at Carbondale, Carbondale, IL, USA

Abstract

Human rights have provided a contentious issue in the social work profession, and have a patchy implementation globally. This is changing as social workers and educators throughout the world embrace concepts of human rights. The International Federation of Social Workers and International Association of Schools of Social Work have incorporated human rights throughout their mission statements. However, while human rights have now become more accepted within social work education and practice, social workers still have to understand what human rights actually represent. Application of human rights to social work policies and practices remains a work in progress.

Introduction

Human rights have recently been prioritized for inclusion in social work education and practice. In this article, I describe human rights and argue for their further development in the profession.

Overview of Human Rights and Social Work

The connection between human rights and social work has become increasingly important within the last decade. In 2004, at a meeting in Adelaide, Australia, the International Federation of Social Workers (IFSW) and International Association of Schools of Social Work (IASSW) jointly made a major change within the international code of ethics for social workers throughout the world by agreeing an ethics document that covered practice, education, and research. This agreement changed IFSW's 1994 ethics document that did not mention human rights as a social work principle. The 2004 document incorporated human rights as a dominant guidepost for social work policies and practice and turned social work into a human rights profession. These two international umbrella organizations for the social work profession now expect practitioners in their member countries to adhere to human rights principles. Thus, for example, the US-based Council of Social Work Education has required human rights to become part of the social work curriculum that US schools of social work must teach for accreditation (Council of Social Work Education, 2008). Outside the United States, social work educators have also integrated human rights into their works (e.g., Ife, 2008; Wetzel, 1993; Wronka, 2008; Dominelli, 2009).

Why have human rights been recently integrated into the wider social work profession? This integration of human rights with social work may have always been there, without being specifically stated as currently. In the past, social work principles often related to human rights principles, but little formal effort that specifically linked human rights with social work. What is now happening is formal recognition of the strong connection between human rights and social work. For instance, the American social work code of ethics today still does not mention human rights within its ethical statements (National Association of Social Workers, n.d.). Yet, a reading of that code indicates a strong connection to human rights principles. Values stated in the code include social justice, dignity and worth of the individual, and integrity, all of which require reference to human rights. Although human rights have always been explicitly part of contemporary social work, the profession's international organizations have made this connection formal and explicit in the *Global Agenda for Social Work and Social Development* (IASSW, IFSW, ICSW, 2004).

What Are Human Rights?

One of the major challenges within the social work profession is that of defining human rights. Understanding the meaning of human rights is crucial to social workers using these within their practice. Unfortunately, in today's world, politicians and government officials often leave out the term human rights when criticizing others for all types of sins, including torture, suppression of political speech, religious discrimination, and gender bias. These acts violate human rights, but social workers' concerns go far beyond a litany of violations. Often overlooked, human rights include positive rights, like a right to water, food, education, adequate health care, housing, work, clean environment, leisure time, and other important quality of life matters (United Nations, 1948). Rarely do government leaders discuss these equally important human needs within the context of human rights (George, 2003). By failing to connect social, cultural, and economic needs to the overall concept of human rights, governments leave huge gaps regarding the realization of human rights.

Universality and Indivisibility

Human rights cannot exist within a vacuum. They must be linked to an overall goal of how best to manage and enforce these rights. Within this goal lies the notion of universality: Every individual, wherever she or he resides, has a claim to specific human rights principles, which should be accepted as valid globally. Governments should not have the authority to deny an individual their human rights. Rather, governments have an obligation to establish frameworks within which to promote human rights. Problems with universality arise when a government does not accept a particular need as a human

right, for example, the United States does not acknowledge medical care as a human right even though the Universal Declaration of Human Rights (UDHR) specifically classifies medical care as one of these – Article 25, UDHR. American laws may require public hospitals to treat individuals for emergency care, but there is no other legal requirement to provide medical care. In contrast, other Western countries view medical care as a right that governments must provide. Some Asian countries reject UDHR definitions of human rights for being embedded in Western concepts that focus on individual, not group rights (Yip, 2005).

Other commonly accepted human rights include free speech, right of assembly, and elections (Art. 19–21). While more and more countries seem accepting of these universal values (note recent developments in the Middle East), differences exist in their interpretation of these. For instance, China has restricted some opinions from being communicated over the Internet; other countries accept greater latitude in allowable content.

Universality does not mean that everyone is alike or should ignore differences. Universality allows all types of diversity and differences among individuals and groups. Its main purpose is to ensure that individuals and peoples everywhere have basic rights within their lives, but not that these will be the same everywhere (Reichert, 2011). For example, European countries fund medical care in diverse ways (Esping-Andersen, 1990).

Within a human rights framework, indivisibility goes alongside universality. Indivisibility refers to the necessity for governments and individuals to recognize each human right and not selectively promote some while ignoring others. International agreement may exist on the definition of a human right like medical care, but a country may refuse to enforce that right. Without adequate health care, an individual may ignore treatment of an illness. Impaired health can reduce an individual's enjoyment of other human rights, like employment or participation in community elections. The denial of one human right impacts on the enjoyment of other rights, making indivisibility crucial to any human rights framework.

How is it possible to promote human rights when a country can pick and choose what human rights it accepts or ignores? This is a major dilemma within the structure of human rights. Although every country belonging to the United Nations agrees to accept the UDHR as a guiding document, many countries fail to embrace fully all the rights covered by that document. A consequence of the parochial treatment of human rights is the belittling of what human rights mean (MacNaughton and Frey, 2011). Social workers may become frustrated when confronted with entrenched government structures that diminish the enjoyment of human rights. For human rights to have meaning to the profession, social workers have to develop interventions that can overcome obstacles to their realization. Possible approaches for integrating human rights into social work practice are discussed in Section Human Rights within Social Work Context.

Universal Declaration of Human Rights

Any understanding of contemporary human rights, whether by students, social workers, government officials, lawyers, or other interested persons, has to begin with a thorough analysis of the UDHR (United Nations, 1948). The United Nations (UN) adopted the UDHR in 1948 and requires all member nations to adhere to it. Social workers were involved through Katherine Kendall as IASSW's representative. The UDHR lists fundamental freedoms and rights that each member nation is expected to promote among citizens and residents.

The drafting of the UDHR occurred with the horrors perpetrated by Nazi Germany in mind (Morsink, 1999). Nazi Germany had labeled numerous individuals and groups as non-Germans, depriving them of rights and benefits granted to ethnic German citizens, with the eventual goal of exterminating non-Germans (Arendt, 1956). While Nazi Germany's genocidal policies provided the most immediate rationale for universal rules that would protect vulnerable populations, other factors also played a role (Reichert, 2011). Poverty and unemployment had afflicted many individuals throughout the world during the Great Depression of the 1930s. The colonization of African and Asian countries by Europeans also provided fuel for a universal rule against the exploitation of peoples by more powerful ones. The list of issues concerning the human condition seemed endless after World War II. Their discussion produced a broad-based document defining the essential underpinnings for human existence. Given vast cultural and other differences among individuals, finding common needs and freedoms for everyone to share was crucial. The outcome of the ensuing intensive soul-searching was the UDHR. While not perfect, its principles provide a worthy foundation for advancing political and social rights that everyone should enjoy, regardless of where she or he resides.

The UDHR does not contain language that legally binds a nation to enforce human rights. Although many countries have integrated human rights into their own laws, this integration remains a work in progress (Petersmann, 2002). Reference to the UDHR as a standard for acceptable conduct regarding human rights highlights its significance. However, the conflict between the principle of national sovereignty and a state's duty to care for each citizen results in international reluctance to enforce adherence to the UDHR (Dominelli, 2009).

To understand the fundamental concepts of human rights, social workers should read the UDHR and analyze the document as a whole. It begins by recognizing the inherent dignity and equal and inalienable rights of all members of the human family as the foundation of freedom, justice, and peace in the world (Preamble). Human rights should be protected by laws and everyone should enjoy those rights. The UDHR often refers to freedom as an important goal without defining this term. When different cultures and political systems are involved, defining freedom becomes difficult. I argue that freedom in the UDHR does not refer to a Western or American type of freedom, but one that allows for general improvement in social and economic conditions. A common understanding of rights and freedoms plays a key role in realizing universal human rights. Although what constitutes human rights and freedoms can be contested, nations can agree some similarities while acknowledging that differences in interpretations will occur owing to cultural, economic, political, and social diversity among them.

Political and Civil Human Rights

The UDHR lists a number of political and civil rights that all member countries of the UN have accepted as a core foundation for their political and civil rights frameworks (Art. 1–21), and upon which they are expected to construct their political structures. Those human rights include prohibitions against slavery, torture, arbitrary arrest and detention, gender and ethnic discrimination, and arbitrary interference with an individual or family's privacy. Other political and civil rights listed provide the right to asylum, fair legal systems, presumption of innocence against criminal charges, freedom of movement, freedom of expression, fair elections, and peaceful assembly.

However, some countries may interpret these rights in ways that violate the clear intent of the UDHR. Such responses illicit questions such as: Should a country be allowed to detain individuals suspected of terrorist acts for unlimited periods of time without trial or a hearing to examine the evidence of suspected terrorist acts? Should a country be allowed to torture suspects accused of terrorism to extract information that might prevent future terrorist acts? Should previously accepted guidelines defining torture be revised to allow treatment that was previously accepted as torture? Should a country be allowed to execute suspected terrorists without trial or even arrest, as occurs through the use of unmanned drones to kill suspected terrorists? These acts appear to violate political human rights contained in the UDHR. Yet, what enforcement mechanism can prevent such human rights violations, particularly if the accused is a major power like the United States? Various courts may consider individual human rights cases to provide a remedy. But when a country adopts general policies that violate established human rights, or refuses to acknowledge the legitimacy of the International Criminal Court at The Hague, human rights violations will continue. This lack of enforcement poses a significant challenge in promoting human rights.

Cultural, Economic, and Social Human Rights

A second category or type of human right contained in the UDHR involves cultural, economic, and social needs (Art. 22–27). It provides that everyone has the right to social security, education, housing, medical coverage, employment, and leisure time. Everyone also has the right to participate in the cultural life of a community and enjoy the protection of interests resulting from scientific, literary, or artistic creations.

Cultural, economic, and social human rights differ from political and civil human rights in that a community or government will have to be more proactive in insuring their realization. Political and civil human rights aim to prevent governments from discriminating against particular ethnic groups. As long as the government does not discriminate, no human right is violated. However, cultural, economic, and social rights often require a government to provide every citizen or resident with services like health care or education. This can be costly and some governments may lack resources for funding these. Some people contend that economic and social human rights dilute the traditional human rights focus on political and civil rights (*The Economist*, 2007). This view maintains that food, jobs, and housing are necessities, but not rights that can be violated, unlike a government detaining individuals without a fair trial. This clarity on political rights seldom holds for economic and social rights.

Social workers can question the opinion that economic and social human rights are not true human rights because they will most likely encounter situations where economic and social human rights are at issue. In contemporary human rights, the lack of economic and social rights can be linked to dictatorships in several countries, including Germany under the Nazis. In others, for example, during the Great Depression of the 1930s, the United States had to respond to its residents' economic and social welfare by creating work projects and other economic assistance programs (Sunstein, 2004). Economic and social human rights are difficult to separate from political and civil rights. Neither type of human right should be subordinated to the other, because the deprivation of one can easily lead to the deprivation of other. Additionally, where countries fail to address economic and social inequality, economic growth may suffer (Lowrey, 2012; *The Economist*, 2012).

Other Provisions of the UDHR

Aside from promoting political, civil, economic, and social human rights, the UDHR encourages working toward a social and international order in which human rights can be realized (Art. 28). Without UN member countries cooperating on international concerns and disputes, human rights principles can easily be ignored. An example of this concept is the failure of the international order to uphold a multinational environmental treaty to reduce greenhouse emissions that affect more than one country. Environmental rights were not part of the UDHR, but social workers are demanding their inclusion (Dominelli, 2012).

Another provision of the UDHR states that everyone has a duty to respect the human rights of others and the community in which the individual resides (Art. 29). Human rights impose duties upon governments and individuals regarding recognition of their importance to the community as a whole.

Challenges to the UDHR

Major challenges to the UDHR concern its enforcement and interpretation. Whose voices are being heard when interpreting human rights? An individual with income in the top 10% of income earners might object to redistributing that income among lower income individuals through taxation. Higher income earners might view those earning less as lazy or undeserving, but human rights are not designed to function in that way. All voices should be heard when conceptualizing human rights. Human rights belong to everyone, not a select group. If someone does not have adequate medical care or food with which to survive, then government and other members of the community should provide that medical care and food. Every individual is responsible for satisfying those needs, but circumstances may prevent the individual from doing so, for example, lacking resources for buying medical care or food. Labeling a person as lazy or undeserving is unhelpful in addressing human rights issues because the structural causes of an individual's predicament can be ignored. Governments and

community organizations should address structural obstacles to satisfying human rights by asking: Why does a person not have adequate medical care? Is it the individual's fault or are there cultural and social reasons for it? Why does a person not have sufficient food? Is the individual making unwise choices in purchasing items, perhaps preferring lottery tickets or tobacco products over food? Does the individual simply have no income? The human rights mission of professional social work is to examine circumstances behind failure to meet human rights goals and try to remedy these (IFSW and IASSW, 2004).

Even where countries generally agree the interpretation of a human right, enforcement can be difficult. For example, countries may agree that women have equal status to men, but underlying social and cultural norms may prevent its realization. Women may not enjoy the same level of respect as men in holding public office, managing large companies, occupying upper administration positions within education, and any number of significant roles within society. Contesting such human rights violations can be detrimental to women's career or lives, not to mention the emotional stress of raising objections to entrenched norms. Despite the Convention to Eliminate Discrimination Against Women and others linked to ethnicity, disability, and age, an egalitarian human rights framework can be difficult to create because this would require some people to relinquish current privileges.

No simple answers can confront human rights challenges. However, social work occupies a unique position in educating about and confronting human rights violations. Ethical statements require social workers to educate themselves about human rights and address their violation. This task is not easy, but one that ethical social workers are duty bound to pursue.

Covenants and Other Documents on Human Rights

The UN has drafted numerous documents following the UDHR to provide wider acceptance and guidance on realizing human rights. While there are many, I have space to focus on two key covenants or international treaties that are binding on nations adopting them: the International Covenant on Civil and Political Human Rights and the International Covenant on Economic, Social, and Cultural Rights (United Nations, 1976, www.un.org). Many nations have endorsed these covenants and, at least on paper, have integrated these human rights into their legal systems. The European Court of Human Rights requires member countries to adhere to provisions within the UDHR and these covenants (European Court of Human Rights, www.echr.coe.int). The UN does not require member nations to adopt these or any other covenants, and some have not. One notable exception to the adoption of the covenant on economic and social rights is the United States, which refuses to accept various UN covenants or treaties on human rights. Its failure to promote UN documents on human rights or endorse their wider acceptance lies partially within the American legal framework for approving treaties and partly within its political structure where national sovereignty must prevail over UN treaties. Nations that sign international treaties, like the covenants on human rights, must relinquish some control over their legal systems, since they are obliged to incorporate human rights into their laws. American politicians have not been willing to do this and have failed to approve the vast majority of UN human rights treaties, including the Convention on the Rights of the Child.

International Covenant on Civil and Political Rights

The UDHR laid the foundation for the modern era of human rights. However, the UN did not draft the UDHR in legally binding language. To legally require countries to acknowledge and enforce human rights, the UN has proposed various covenants or conventions, which are to have the force of law once a member country had given approval. One of the first major covenants that the UN drafted after the UDHR was the International Covenant on Civil and Political Rights. Its counterpart was the International Covenant on Economic, Social, and Cultural Rights.

The International Covenant on Civil and Political Rights duplicates UDHR provisions that address what might be classified as freedom from wrongful treatment by a government. No country may

- torture someone (Art. 7);
- practice slavery or forced labor (Art. 8);
- arbitrarily arrest or detain an accused (Art. 9);
- discriminate against persons on the basis of a status, including gender (Art. 26); or
- interfere with an individual's right or privacy (Art. 17), freedom of expression (Art. 19), or use of its legal system (Art. 16).

Other sections of this covenant include the right of self-determination among peoples (Art. 1) and the right of minority groups within a state to enjoy their own culture, religion, and language (Art. 27). Countries that agree to follow this covenant must submit periodic reports to a Human Rights Committee as to progress made in satisfying its human rights provision (Art. 40, para. 1).

Social workers can embrace this covenant's political and civil rights that guarantee that everyone can voice opinions, preserve cultural backgrounds, enjoy freedom of speech, freedom of movement, and freedom from arbitrary arrest and torture. They can also integrate these into social work policies and practices.

International Covenant on Economic, Social, and Cultural Rights

The counterpart to the International Covenant on Civil and Political Rights is the International Covenant on Economic, Social, and Cultural Rights. This latter covenant also derives its provisions from the UDHR but focuses on needs or quality of life issues. For this reason, some countries, most notably the United States, do not consider this one as pressing as that on civil and political rights. Unlike many other countries, the United States does not recognize the Covenant on Economic, Social, and Cultural Rights as a valid expression of human rights, and so refuses to ratify it.

The Covenant on Economic, Social, and Cultural Rights requires that countries provide technical and vocational guidance, training programs, and policies to achieve economic,

social, and cultural development, as well as full and productive employment (Art. 6). Women are guaranteed conditions of work equal to those of men, and workers should have a decent living (Art. 7). This emphasis on work is a key part of the covenant, which acknowledges that societal harm can occur through unemployment or unfair working conditions. Some countries may not have the resources to fulfill the work requirements, but, at a minimum, governments should assist residents in obtaining suitable employment opportunities. Other parts of the covenant require states to provide education (Art. 13), food and housing (Art. 11), health care (Art. 12), and social security (Art. 9) to every resident, although many Western governments are pursing austerity measures despite the risks in socioeconomic rights.

Like the Covenant on Civil and Political Human Rights, the Covenant on Economic and Social Rights provides for reports on steps taken to fulfill these rights, but allows states more leeway in satisfying them. This can be an implicit acknowledgment that many countries might have difficulties meeting the covenant's requirements.

Other Important Human Rights Documents

While the UDHR and covenants on political and socioeconomic human rights form the core of contemporary human rights, the UN has proposed numerous other documents for adoption and inclusion into member states' legal system. Briefly, these include the:

- *Convention on the Elimination of All Forms of Discrimination against Women* (CEDAW, 1979). This aims to eliminate distinctions, exclusions, or restrictions made on the basis of sex, which aim to impair women's human rights (Art. 1).
- *Convention on the Rights of the Child* (CRC, 1989). Member nations approving this Convention are obliged to recognize the special needs of children and respect their human rights. This convention specifically recognizes the responsibilities, rights, and duties of a child's parents or guardians in raising the child. No provision of this Convention aims to deprive parents of their accustomed role as the child's caregivers.
- *Convention on Elimination of All Forms of Racial Discrimination* (CEAFRD, 1965). This seeks to prevent ethnic discrimination.
- *Convention on Rights of Persons with Disabilities* (CRPD, 2009). This promotes the rights of disabled people.
- *Principles for the Older Person* (POP, 1999). These have less force than conventions, but can assist in reducing age discrimination.
- *Declaration on the Right to Development* (DRD, 1986). Developmental rights are contentious, but this declaration helps countries to industrialize.
- *Millennium Declaration* (MD, 2000). The *Millennium Declaration* stresses broad goals (Millennium Development Goals) to be achieved by the year 2015, including eradication of poverty and hunger, achieving universal primary education, ensuring environmental sustainability, reducing child mortality, empowering women, and developing of a global partnership for development.

The adoption of UN documents on human rights coupled with difficulty in their enforcement has led to the formation of organizations like Human Rights Watch. This regularly investigates human rights abuses around the world and provides annual surveys on compliance with human rights principles (Human Rights Watch, www.hrw.org). Surveys issued by Human Rights Watch highlight human rights violations in individual countries, and provide annual updates. Human Rights Watch covers practically every country, including Western countries like the United States that seem to place themselves above others in the human rights arena.

The social work profession has much to gain from integrating human rights into its policies and practices. Its review of UN documents on human rights can clarify the issues that directly impact upon a social worker's education and career.

Human Rights within Social Work Context

The connection between human rights principles and social work policies and practices requires more than a study of UN documents. Social workers must understand the meaning of human rights and develop the tools for integrating human rights into the profession. The IFSW and IASSW have developed and stated the core purposes of social work throughout the world, *The Global Standards Document* (Sewpaul and Jones, 2004). Those purposes include:

- Facilitating the inclusion of socially excluded, dispossessed, and vulnerable groups of people;
- Addressing and challenging barriers, inequalities, and injustices in society;
- Forming working relationships with individuals, families, groups, organizations, and communities to enhance their well-being and problem-solving capacities;
- Assisting and educating people to obtain services and resources in their communities;
- Formulating and implementing policies and programs that enhance people's well-being, and promoting development and human rights, and collective social harmony;
- Encouraging people to advocate on pertinent local, national, regional, and international concerns;
- Engaging in social and political action to influence social policy and economic development and effect change by critiquing and eliminating inequalities; and
- Promoting respect for traditions, cultures, and religions among different ethnic groups and societies insofar as these do not conflict with human rights.

These core activities place social workers at the forefront of understanding clients, their needs, and cultures within which they exist. Social workers should not be passive in this pursuit but should take a leading role rather than a secondary role to lawyers or government officials when addressing human rights issues affecting clients. The IFSW and IASSW documents encourage social workers to adopt more active roles in addressing the many political, economic, and social issues that afflict countries throughout the world. One example of this is community-based human rights advocacy practice, an approach to community organizing that combines theoretical and practice frameworks from law and community organizing in social work practice. Human rights, such as the right to housing, health, and education, are at the forefront of such

practice. Individual and community constituents are trained to advocate for entitlements and maneuver within systems to access rights (Grodofsy, 2012). A social worker applying human rights to their practice should first analyze a particular set of circumstances in relation to human rights principles. Questions to ask include: What human rights issues are relevant to the situation? What are the specific provisions in human rights documents that apply? What controversy or conflict might arise from the human rights relevant to this situation? Does cultural relativism play a role in the social worker's perception of what constitutes human rights?

Cultural Relativism

Another key concept in analyzing human rights within a social work situation is that of cultural relativism. In cultural relativism, all points of view are equally valid, and any truth is relative, with truth belonging to the individual or her or his culture (Reichert, 2011). All ethical, religious, and political beliefs are truths related to the cultural identity of the individual or society. Cultural relativism is appropriate for certain human rights; for instance, language, food. However, others like clothing, art, and architecture differ from one culture to another and maintaining these differences remains important (Pasamonik, 2004). Also, cultural relativism suggests an irreducible diversity among cultures because each culture is unique as a whole, but with parts so intertwined with others that none can be understood or evaluated without reference to the others and the cultural whole, the so-called pattern of culture (Lawson, 1998).

The phrase 'cultural relativism' creates confusion when discussing human rights because it refers to a view that all cultures are equal and that universal values are secondary when examining cultural norms. No outside value is superior to that of the local culture. So, for example, if local cultures allow female genital mutilation, the human right prohibiting cruel or degrading treatment cannot prevent it (Reichert, 2011). Such conundrums indicate that like universality, cultural relativism has limits. A social worker should examine the historical background of a cultural practice that appears to violate contemporary human rights principles and ask Which group has determined the cultural practice? Has the decision-making process been democratic, with voices from many groups heard in determining it? This analysis will often find that cultural relativism rests on outdated or oppressive foundations.

Conclusion

The social work profession is well suited to integrating human rights principles into its policies and practices. This integration presents many challenges, including lack of government support for their fulfillment. Moreover, enforcement is weak because nations are reluctant to intervene in sovereign nations' internal affairs. And, cultural relativism can confuse practitioners wishing to act. However, by understanding what human rights mean to particular individuals in specific contexts, and acting to apply human rights to such situations, social workers can confront human rights challenges within the profession. The IFSW–IASSW guidelines are useful in developing this dimension of social work theory and practice.

Abstract

Anthropology has had a curious and contested disciplinary relationship with the postwar human rights project. This article analyzes the history of this relationship from the period of the drafting of the University Declaration of Human Rights to the present. After describing both political and critical approaches to human rights by anthropologists, the article discusses contemporary anthropology of human rights that emerged after the end of the Cold War. This article reviews the major topics and areas of theoretical contribution in the anthropology of human rights and concludes with a discussion of future directions.

Overview

Although anthropologists took an interest in human rights from the creation of the modern human rights system after the Second World War, only recently has it been possible to speak of the anthropology of human rights. Unlike the anthropology of religion, kinship, politics, or law, for example, the anthropology of human rights developed almost accidentally as a response to changes in historical and geopolitical incidences that took place largely after the end of the Cold War. Anthropologists in the field, in the midst of ongoing research on problems such as social change, legal identity, transnational networks, and indigenous mobilization, found themselves confronting emergent forms of political, legal, and cultural practices that were being shaped by a suddenly urgent discourse of human rights. Throughout the 1990s and 2000s, anthropologists tracked this rapid expansion of human rights from a number of different methodological and theoretical perspectives. As the liminal period of the post-Cold War arguably gives way to a historical phase of re-differentiated hierarchy and constraint in which human rights play an important – although not globally hegemonic – role in politics, social ethics, and legal regulation, the anthropology of human rights will continue to develop as an important disciplinary subfield and mode of critical analysis.

This article on the anthropology of human rights is structured as follows. In the next section, the history of anthropology's often fraught relationship with human rights is surveyed and a timeline of key turning points in this history is described. As a matter of historiography, the emphasis on a particular chronology is meant to provide an interpretative framework rather than establish a set of unassailable historical facts. The historical narrative of anthropology and human rights has itself been a matter of some dispute. Some of this contention will be explained and an effort will be made to achieve some measure of balance among the most notable differing perspectives. After examining the history of anthropology's various engagements with human rights, the article will then identify and describe key themes that emerge from this dynamic subfield and which mark off the anthropology of human rights as a distinctive source of ideas for human rights scholars, practitioners, and policy-makers. Much of the early anthropological skepticism toward certain aspects of the postwar human rights project has been carried forward in the form of a growing body of critical anthropological theory. Nevertheless, this has not created a divide between the findings that have emerged from the ethnography of human rights practices and the demands of human rights activists and policy-makers for human rights theory with wider application. Instead, somewhat surprisingly, recent work in the anthropology of human rights has been taken up in policy documents and commissioned reports among a range of international institutions, including the Office of the United Nations High Commissioner for Human Rights, the World Bank, and the Committee on the Elimination of Discrimination against Women. Even the President of Ireland, Michael D. Higgins, a noted human rights activist and author, has made several studies in the anthropology of human rights central to policy speeches and annual addresses. Finally, the article considers future directions in the anthropology of human rights with a focus on promising avenues for new research and public scholarship.

History

Outside of anthropology, a debate is currently raging between scholars who view the development of ideas and practices of human rights over the *longue durée* and those who see human rights as a much more recent and unprecedented phenomenon. To the former, the history of human rights must be analyzed as part of an incremental, centuries-long process in which conceptions of universal rights were extracted from an even longer intellectual history with roots in classical antiquity and then ecclesiastical Europe; these ideas were eventually made the basis for political ideologies with practical consequences for politics and modes of governance; and, finally, these ancient ideas of human rights found expression in the 1948 Universal Declaration of Human Rights (UDHR), which must be understood as both a culmination and an apotheosis. For the latter, the so-called revisionists, the story of human rights is much more contemporary. As a rhetoric of political activism and moral outrage, the history of human rights really begins in the 1970s. On this view, the UDHR is merely a relic with little relevance for understanding the set of historical and political factors that made the emergence of

human rights both possible and, in a sense, inevitable. (For examples of these debates, see Alston, 2013; Bass, 2010; Glendon, 2001; Hunt, 2007; Moyn, 2010.)

The history of the relationship between anthropology and human rights is marked by a similar debate, not over origins, but over the role anthropologists played during the drafting of the UDHR, the extent to which anthropology as a discipline had a distinct perspective at all on human rights in the aftermath of the Second World War and throughout the early years of the Cold War, and the form and implications of more recent orientations to human rights by individual scholars and professional associations.

The Creation of the UDHR

The devastation of the Second World War formed the backdrop for the effort to create an international system that would once and for all prevent global war, military imperialism, and genocide. Much like the earlier and short-lived League of Nations, the new United Nations system was predicated on a set of universal moral propositions, the most important being the proposition that all human beings are born equal in dignity. As a consequence of this proposition, leading proponents of the postwar settlement thought it necessary to go a step further and draw up a declaration of universal rights that would serve as the framework through which human dignity would be enshrined, promoted, and eventually protected.

An international drafting committee was assembled, chaired by Eleanor Roosevelt. During the contentious process of forging consensus around a working draft of what became the UDHR, the United Nations Educational, Scientific, and Cultural Organization (UNESCO) was asked to help the drafting committee by conducting a comprehensive survey of world opinion on the question of the types of universal norms that should be represented in a declaration of human rights (see, e.g., Morsink, 1999). UNESCO convened a panel of leading philosophers, theologians, writers, and diplomats and this group – which has come to be known as the 'Philosophers' Committee' – designed a lengthy questionnaire, which was distributed to individuals around the world. The responses to this questionnaire were collected and analyzed during a meeting of the panel at UNESCO headquarters in Paris, in 1947. After this meeting, a report was sent to the drafting committee to assist it as it neared completion of a first draft of the UDHR (UNESCO, 1949).

One of the individuals who responded to the UNESCO questionnaire was the American cultural anthropologist Melville Herskovits. (The questionnaires were sent to individuals based on their cultural backgrounds, scientific expertise, and religious affiliations. They were not sent to institutions or representatives of nation-states.) Herskovits participated in both the American Anthropological Association (AAA) and the US National Research Council and was a leading international anthropologist of the time who was strongly influenced by his former professor Franz Boas's theory of cultural particularism. He sent his formal response to the UNESCO questionnaire to the Executive Committee of the AAA, and it then asked the editor of the AAA's scientific journal, *American Anthropologist*, to publish Herskovits's 'Statement on Human Rights' in the journal's 1947 December edition, which he did (see Goodale, 2009). In publishing the Statement, the Executive Committee adopted it on behalf of the AAA without consultation or a vote of the general membership (the AAA was a much different organization in the mid-twentieth century).

The Statement on Human Rights rejected the legitimacy of a UDHR on three distinct grounds: the epistemological, the empirical, and the ethical. First, it argued that the claims of human rights involved abstract moral assertions that could not be scientifically demonstrated by anthropology. It was, therefore, impossible to know whether or not the universal propositions of human rights were true through the techniques of scientific investigation. Second, the Statement suggested that the weight of anthropological research could not be used even for indirect support for the claims of universal human rights. Anthropologists had conducted a wide range of studies of legal and political systems by the middle of the twentieth century, and this research revealed a panorama of cultural diversity. It was simply not possible, according to the Statement, to read this body of anthropological research as evidence of preexisting normative universality. And finally, the Statement dwelled at some length on the broader political economy of human rights and the role of Western powers in promoting particular legal and political approaches to social problems. It argued that regardless of good intentions, an overarching declaration of human rights from the new United Nations would eventually work against the vitality of the local value systems that held together small-scale societies (AAA, 1947).

Regardless of these concerns from at least one prominent member of the discipline that was widely regarded during the mid-twentieth century as the primary source of scientific information about the world's cultures, the Drafting Committee finalized the UDHR, and it was presented to and adopted by the General Assembly on 10 December 1948 (for a general history of the drafting process, see Morsink, 1999).

1948–1980s

The publication of the Statement on Human Rights in *American Anthropologist* led to three brief comments in 1948 and 1949 (Barnett, 1948; Steward, 1948; Bennett, 1949). But from then on, there is scant evidence that anthropologists from any national tradition took an active research interest in human rights for at least several decades. Indeed, it is true enough to say that anthropologists played almost no role in the development of human rights in the initial decades after 1948 and that the discipline had no discernable position toward or interest in human rights, the Herskovits-authored Statement on Human Rights notwithstanding. Nevertheless, it has been common for scholars in more recent years to assert that the Statement on Human Rights represented a widespread anthropological position on human rights at the time and that this early orientation was the source of decades of shame and disciplinary embarrassment (see, e.g., Engle, 2001; Messer, 1993). But archival and historical research revealed that despite active academic and political involvement in the debates over race in the 1950s, the civil rights and antiwar movements in the 1960s, and the antinuclear and environmental movements of the 1970s, anthropologists were largely

silent on the question of human rights and its relation to the discipline until the 1980s (Goodale, 2009).

1980s–1999

The period 1980s was a time of epistemological ferment for anthropology, particularly in the United States, where critical scholars built on earlier interests in political economy and broader Marxist approaches to social theory to scrutinize the institutional orientation of the discipline toward the often marginalized peoples that were its traditional objects of knowledge. Although this crisis of representation in anthropology was more often than not articulated through the language of then-cutting edge social and critical theory, typically continental German or French, the debates at the time had an indirect implication for the anthropology of human rights. The auto-critique of anthropological positivism during the 1980s created cover for the emergence of much more formally political forms of anthropological knowledge, even more so than earlier movements toward Marxist anthropology, which, at least in its well-defined British version, remained largely an innovation confined to anthropological theory.

At the same time, by the 1980s, human rights had become a much more visible framework through which grievances, social struggles, and projects for justice could be articulated. From the global antiapartheid movement to the antinuclear green movements of Western Europe, 'human rights' entered the political and social vocabulary at the same time that the ratification of major international human rights documents accelerated and new human rights laws were drafted. For the history of anthropology and human rights, the most important of these was International Labor Organization Convention No. 169, the so-called indigenous people's 'Bill of Rights.'

As early as the 1970s, anthropologists like David Maybury-Lewis had used their anthropological expertise to advocate for the 'cultural survival' of small-scale populations, many of whom lived in isolated, resource-rich areas that made them vulnerable to exploitation and displacement. Throughout the 1980s, the expanding indigenous rights movement within the broader human rights coalition provided a further opening for anthropologists to become involved politically as advocates and as cultural experts. Reflecting on this shift in the discipline during this period, scholars like Terry Turner argued that human rights became a means through which anthropologists could participate in an 'emancipatory cultural politics' on behalf of indigenous populations (Turner, 1997). This heightened awareness of human rights paved the way for a series of institutional shifts, again, primarily within American anthropology, which included the creation of a standing Committee for Human Rights within AAA (1995) and, most importantly, the drafting of the 1999 'Declaration on Anthropology and Human Rights.'

This official statement of the Association's (if not the discipline's) orientation toward human rights was – unlike the 1947 Statement on Human Rights – approved by a majority of Association members through a general vote. In addition, at a substantive level, the 1999 Declaration was an explicit and dramatic repudiation of Herskovits's 1947 Statement. Not only does the Declaration recognize the cross-cultural validity of human rights, but it also maintains that anthropologists have a disciplinary obligation to use their research expertise to expand the definition and meanings of human rights even beyond those established in current international law (AAA, 1999). Following the promulgation of the Declaration, the Association became increasingly active in human rights advocacy on behalf of vulnerable populations and victims of human rights abuses (including academics) around the world.

In the years leading up to the 1999 Declaration, some of the same activist-anthropologists who played key roles in the drafting of the Declaration and its promotion within the discipline prepared a special 1997 issue for the *Journal of Anthropological Research* that laid the intellectual and disciplinary groundwork for this new orientation and understanding of anthropology's responsibilities toward human rights advocacy (see the articles by Hatch, Messer, Nagengast, Turner, and Zechenter). Among other things, these essays reflected a certain defensiveness by some anthropologists about the way in which concepts such as cultural relativism had come to be associated with justifications for human rights abuses. Despite the fact that the danger that human rights advocacy could devolve into cultural imperialism "chill[ed] the anthropological soul," as Nagengast argued in her contribution (1997: 349), the path had been cleared – both institutionally and intellectually – for a new phase in anthropology's engagement with human rights.

1999–2007

At the same time when anthropologists were developing institutional and epistemological frameworks that made anthropology newly relevant to human rights advocacy, and vice versa, another, quite different process of historical importance was taking place. The end of the Cold War was a geopolitical watershed moment for the broader international human rights movement. The dissolution of the Realpolitik logics of the Cold War conflict created a vacuum in international relations in which new (or recreated) transnational forms of moral practice and political struggle could emerge. In just over a decade, human rights discourse saturated everything from constitutional reform to international development projects. By the mid-1990s, the rhetoric of human rights had already become the "only legitimate language of democratic transition," as Richard A. Wilson put it (2001: 1); many countries, particularly in Latin America, had implemented international human rights norms through wide-ranging domestic reforms in women's health, bilingual education, and rural development; and a movement to create a permanent international criminal court to prosecute gross human rights violations culminated in the adoption of the Rome Statute by the UN General Assembly.

Even as some anthropologists participated in this proliferation of human rights as advocates, cultural experts, and witnesses, other scholars responded by developing methodologies of critical analysis that coalesced into a proper anthropology of human rights. Here, ethnographers studied the close details of human rights advocacy and political reform across an ever-widening range of regional and social scale. The critical ethnography of human rights was largely agnostic about the social, political, and moral claims of the broader human

rights project that it documented across a rich cross-cultural panorama. Important examples of this first extended period in the anthropology of human rights would include Richard A. Wilson's study of human rights in the creation of a postapartheid South Africa (2001); the edited volume on culture and rights that collected early essays that were the fruits of the first sustained ethnographic study of human rights in the post-Cold War period (Cowan et al., 2001); Sally Engle Merry's (2006b) innovative multisited and transnational ethnography of the system used to monitor compliance with the Convention on the Elimination on All Forms of Discrimination Against Women (CEDAW); Harri Englund's provocative study of the ways in which the hegemony of human rights discourse made Malawians 'prisoners of freedom' (2006); and Winifred Tate's ethnographic account of the 'culture and politics' of human rights advocacy in conditions of civil war, postconflict negotiation, and transnational criminality (2007).

As a matter of disciplinary recognition and development, the emergence of the anthropology of human rights as a mode of critical reflection on the rise and an increasing hegemony of human rights around the world (which included the individual and institutional participation of anthropologists as activists) culminated in both a major 2006 retrospective in *American Anthropologist* entitled 'Anthropology and Human Rights in a New Key' (with articles by Cowan, Goodale, Merry, Riles, Speed, and Wilson) and a volume of ethnographic essays on the 'practice of human rights' (Goodale and Merry, 2007) that would come to shape debates on human rights outside of anthropology and in the field of international human rights itself.

2007–Present

The anthropology of human rights has continued to mature and play a part in wider debates in the discipline from the late 2000s to the present. Evidence for this can be found in the number of doctoral dissertations and junior research projects that are self-consciously located within an anthropology of human rights; the growth in conferences, association panels, and workshops in this new subfield; and in the move by anthropology departments and interdisciplinary fields to develop specialisms that emphasize the anthropological study of human rights.

The next-generation ethnographies of human rights practices build on the theoretical and disciplinary foundation established during the 1990s and 2000s. They are marked by increasing levels of methodological and epistemological innovation, as human rights discourse becomes further naturalized within what James Ferguson (2006) called the 'neoliberal world order.' Among the more notable of these recent works are Harri Englund's ethnography of human rights and popular media in Malawi (2011); Galit Sarfaty's study of the fight by human rights lawyers to change the internal culture of the World Bank (2012); Kamari Maxine Clarke's ethnographic critique of the 'fictions of justice' that reinforces the legitimacy of the International Criminal Court (2012); Karen Faulk's ethnography of tensions between neoliberal citizenship and human rights advocacy in Argentina; and Lori Allen's account of the way a culture of cynicism shapes human rights activism in occupied Palestine (2013).

Major Topics

As an emergent and increasingly influential subfield of social and cultural anthropology, the anthropology of human rights has made contributions to theory and methodology in a number of different areas. It has also made its mark outside of anthropology and the academy as international lawyers, policy-makers, and government officials turn to the anthropology of human rights as a source of information and ideas about human rights in policy documents, reports to governing agencies, and in major public speeches (see, e.g., Higgins, 2012, 2013).

Culture

As a category for organizing difference, culture was problematic for human rights from the very beginning. In his 1947 Statement, Herskovits worried at length that existing cultural diversity and richness were not compatible with countervailing universalisms like human rights, which asserted transcultural patterns of normative belief and practice that both flew in the face of anthropological evidence and threatened to homogenize culture within the broader political economy of the postwar settlement.

But despite these concerns, cultural diversity was not affected by the promulgation of the UDHR in 1948, to a large extent, because the broader influence of human rights, not to mention the kind of global transformation imagined by Herskovits, stalled out almost immediately within the Cold War. Even Eleanor Roosevelt herself recognized that the project of human rights would be years, even decades, in the making, and that cultural patterns would not begin to shift until what she called a 'curious grapevine' could take root and spread to places where "governments are not so anxious for it" (quoted in Korey, 1998). By the time this kind of large-scale change did begin, anthropologists of human rights observed that the impact on culture defied stark dichotomies between particularity and universality, and culture itself facilitated the transnationalization of human rights norms.

In the groundbreaking volume *Culture and Rights* (2001), anthropologists reflecting on a decade of ethnographic research after the end of the Cold War noticed two key phenomena at work. In the first, existing cultural practices and modes of normative understanding served as mechanisms for what Sally Engle Merry (2006a) would later describe as 'vernacularization': the translation of increasingly hegemonic international human rights norms into forms of ethical and political practices rooted in the particular. And in the second, scholars in *Culture and Rights* described and theorized the emergence of a transnational culture *of* human rights. Here, an anthropological account of culture proved useful in understanding the formation of new categories of collective action within international agencies, transnational NGOs, and in political and social movements shaped by the logics of human rights. In both, the use of the culture concept by anthropologists of human rights to understand human rights praxis moved against the grain of wider trends in anthropological and social theory, which had become skeptical of the analytical utility of culture in the face of the supposed hybridization of globalization.

Power

Human rights, as Burke might have said, acting through people, is power; and "considerate people, before they declare themselves, will observe the use which is made of *power*; and particularly of so trying a thing as *new* power in *new* persons, of whose principles, tempers, and dispositions they have little or no experience" (Burke, 1910[1790]: 7, emphasis in original). Anthropologists of human rights have been keenly attuned to another problem originally identified by Herskovits: the ways in which a global project of human rights creates heightened tensions at points of existing conflict by overwhelming alternative forms of social change and dispute resolution. Of course, from the perspective of human rights advocacy, this is power exercised for the good; indeed, as expressed most forcefully in international treaties like CEDAW, the postwar human rights project demands change, replacement, even the suppression of modes of cultural practice that remain unaccountable and, therefore, illegitimate. As CEDAW's oft-cited Article 5 puts it, states parties to the international women's bill of rights shall "modify the social and cultural patterns of conduct of men and women, with a view to achieving the elimination of prejudices and customary and all other practices" that are based on local theories of gender inequality.

But as anthropologists have shown, there are often costs to the ways in which human rights tends to bracket and then marginalize other cultural logics of social justice, development, conflict transformation, and public ethics. And this extension of power can have unintended consequences. One of the more far-reaching examples of the way anthropologists have explored the implications of the unpredictable power of human rights is Harri Englund's (2006) ethnography of development in Malawi. As he explains, the concept of human rights was officially translated in the local language with a phrase that meant "the freedom one is born with" (2006: 51). Over time, people took this emphasis on human rights-as-freedom to mean the freedom to challenge existing cultural norms around fashion, obedience in public schools, and sexual behavior, rather than the structural, economic, and political conditions that reinforced a legacy of inequality and public corruption. The result, according to Englund, was that Malawians were eventually "disempower[ed] through translation." Human rights discourse saturated every aspect of public life in Malawi, which is what government officials and transnational aid workers sought. But as human rights were (mis-)rendered in a local moral vernacular, it was transformed beyond recognition in ways that foreclosed its use as a language of much needed social change.

Epistemology

When Herskovits argued that anthropology was not able to make definitive claims about universal human rights because it was a "science of mankind" and, therefore, concerned only with empirical questions of human behavior as expressed through "patterns of culture," he could not have foreseen the epistemological innovations in the discipline that would expand its objects of knowledge and transform its domains of inquiry. This is not to say, however, that in later decades anthropologists brushed aside Herskovits's early arguments in order to confront the basic ontological and philosophical problems that remained essential to human rights. Much of the intellectual labor devoted to human rights remained within spheres like critical legal studies, political theory, and moral philosophy. Rather, anthropologists used ethnographic research to make a subversive case for broadening the grounds on which the fundamental moral and theoretical questions of human rights could be asked and answered. This, in turn, carried important implications for the epistemology of human rights, especially in the post-Cold War, when human rights discourse become increasingly interwoven into everyday forms of legal, political, and social practices.

Anthropologists of human rights observed early on that ideas about human rights were fundamental to human rights praxis. Ordinary social actors, often caught up in moments of crisis or dislocation, were never able to simply harness human rights instrumentally or co-opt its imaginaries of justice as if it were a normative toolkit waiting to be opened when needed. Instead, the logics of human rights advocacy demanded self-consideration as much as social change; people were invited, encouraged, compelled to remake themselves as citizens of a different moral universe. Ethical theorizing in terms of this often radically alternative moral universe became a distinct form of social practice, and the anthropologist became both a witness to and co-participant in this transformation as part of the ethnographic encounter (see Goodale, 2006).

What resulted was an ethnographic record of innovative, and potentially transformative, folk models of human rights that were deeply embedded in the circumstances of their creation. Perhaps, the best example we have of a fully articulated local account of human rights is Shannon Speed's ethnography of the aftermath of the Zapatista rebellion in Chiapas (2007). Both during and after the violence, international and transnational human rights organizations flooded into the Chiapas region. Those promoting indigenous rights-as-human rights were particularly influential in shaping the way Zapatista's resistance was expressed. Indigenous political leaders formed 'good governance councils' in which the ideas of human rights were debated at length, remade, and then used to represent Zapatista moral values as these grounded Zapatista political action.

Transnational Advocacy

The transnational human rights networks that emerged after the end of the Cold War did precisely what Eleanor Roosevelt had expected them to do: they challenged the sovereignty of the state and made it possible to create new public spheres that were both translocal and firmly rooted in sites of intimate contestation. Scholars like Annelise Riles (2000) studied these networks from the 'inside out' and helped shape the broader understanding of the global assemblages that were changing the ontology of social relations during a time of geopolitical and global economic transformation.

But anthropologists of human rights also revealed the extent to which networks of human rights advocacy are shaped by the political economies of local conflict in ways that can change their normative valence and render them, in certain circumstances, incapable of fulfilling their broader mandate for social change and moral transformation. For example, Winifred Tate's (2007)

long-term ethnography of the ongoing conflict between the Colombian state and the Revolutionary Armed Forces of Colombia (FARC) shows how human rights activists struggle to translate the language and moral logics of universal human rights into a category of instrumental action, one that can respond to the challenges of historical trauma, multiple and ambiguous accounts of culpability for atrocity, the legacy of structural violence, and enduring patterns of economic inequality with roots in the colonial period.

Also Sally Engle Merry's (2006b) study of the institutions that monitor national compliance with CEDAW illustrates in rich detail the ways in which human rights activists themselves must navigate multiple and not always overlapping cultures of advocacy and resistance. Representatives of national human rights ministries often find themselves in the position of having to advocate at the same time for both compliance with an international human rights treaty and the integrity and legitimacy of cultural practices that would seem to violate the treaty. Nevertheless, these kinds of dichotomies do not negate the reach of international human rights law into national and local conflicts. Instead, as Merry argues, they reflect the ways in which the practice of human rights creates its own categories of contested identity and power with uncertain implications for both transnational human rights advocacy and the promotion of national(-ist) heritage.

Critique and Engagement

Finally, the anthropology of human rights, perhaps more than other academic orientations toward human rights, grapples uneasily with the dilemma of how to develop a rigorous and ethnographic account of human rights that is both critical and ethically attuned to the conditions of vulnerability that lead to abuse and exploitation. This tension has expressed itself in different ways for different anthropologists, some of whom (like Winifred Tate and Shannon Speed, for example) began their careers as human rights activists before making the social and political processes they were committed to the objects of ethnographic research and reflection.

However, the tension between critique and engagement, skepticism and advocacy, and resistance and commitment is not only a challenge for anthropologists of human rights. As ethnographic research has demonstrated, it is a fundamental social and moral fact for the practice of human rights itself. This is, in part, because as a working theory of both social practice and political change, the idea of human rights demands a form of self-reflection and self-constitution that is meant to sow doubt – about existing cultural practices, about folk theories of the person, about hierarchies of power. Yet, the transition from the old to the new – at once illegitimate authentic – is fraught with moral slippage and unanticipated consequences.

An important recent example from the ethnography of human rights practice is Lori Allen's (2013) study of the role of human rights discourse within the politics of Palestinian resistance to Israeli occupation of the West Bank. Although the language of human rights was used as early as the late 1970s in Palestine as a grassroots rhetorical strategy to advocate for victims of the occupation to an international audience, a professional cadre of activists and NGOs eventually came to restrict the use of human rights within tightly controlled social and political spaces. At the same time, the set of Palestinian grievances went unmet for decades, including the continued violation of human rights, the failure to achieve political independence, and an inability to shift favorably political opinion within Israel.

The result was that ordinary Palestinians came to view the claims of human rights with cynicism and even suspicion. But rather than rejecting human rights entirely, locals within the struggle made an organic critique of human rights part of a broader critical and emancipatory discourse in support of Palestinian autonomy, anti-imperialism, and grassroots (as against interventionist) advocacy. With decades of engagement with human rights part of the history of the Palestinian struggle against occupation, activists were able to appropriate, or push against, the logics and expectations of human rights with a high degree of contextual awareness and political realism.

Future Directions

The anthropology of human rights is now well established as a distinct area of research and source of anthropological theory. Institutionally, scholars and graduate students who work in the anthropology of human rights commonly, but not exclusively, come from the ranks of legal and political anthropology. Because human rights has become an increasingly pervasive mode of contemporary world-making, anthropologists encounter traces of this influence across a wide range of cultural practices, political movements, and moral projects.

This is not to say, however, that the status of human rights is uncontested – quite the contrary. As the liminal period of the post-Cold War gives way to cultural re-differentiation, the establishment of new hierarchies, and the narrowing of spaces of political and social experimentation, human rights will continue to jostle with alternative forms of moral praxis and collective- and self-constitution. While the postwar project of human rights matures through its translation into mundane, even banal, processes of constitutional reform, good governance, and neoliberal economic restructuring, its potential for catalyzing radical transformation and moral upheaval will likely diminish. The anthropology of human rights will become less the study of a political and moral discourse during a time of often giddy transition and seemingly limitless possibility, and more the study of an established contemporary secular universalism among a host of competitors.

Abstract

In this article, six basic debates about human rights are clarified from a historical perspective: the origin of human rights as moral rights connected to the natural law doctrine and opposed to positive rights; the wave of criticism of their abstract and absolute character by nineteenth-century liberal, conservative, and socialist thinkers; their extension from the rights of man to the rights of all human beings and from individual rights to individual and group rights; the tension between national and international control over the protection of human rights and between domestic and international jurisdiction; the controversy over the indivisibility of the three generations of rights; and, finally, the problem of the universal or relative character of human rights as viewed from historical and anthropological angles. The article also tries to answer the questions of whether there has been more progress than failure in the field of human rights and of whether the pressure of inhumanity around us is necessary to trigger human rights progress.

The expression 'history of human rights' has two different meanings. It can be understood (as it usually is) as the history of the concept of human rights, or (less frequently) as the history of the enjoyment of human rights (and their abuse) in practice. Therefore, the basic debates about the concept of human rights are first clarified here from a historical perspective. Then, an attempt is made to answer the questions of whether the history of human rights has been characterized by success or failure and of whether failure triggered progress.

Moral versus Positive Rights

Developing the human rights concept took two millennia in Western history and was so full of unforeseen links, ruptures, reversals, and coincidences, that, until only a few decades ago, it convincingly could be called a unique product of that history. One symbolic pivotal point in this development was 1689–1690, just after the Glorious Revolution of 1688. In these years, the English philosopher John Locke (1632–1704) published his *Two Treatises on Government*, which contained the first classical formulation of human rights (then still called 'natural rights'). In retrospect, this work stood at the juncture of a set of amazingly diverse ideas, some of which went back to antiquity and some of which will survive through the twenty-first century. Locke's point of departure was the doctrine of natural law as it had developed since antiquity and had been transformed, in certain respects almost beyond recognition, by medieval Christianity and early-modern philosophers. According to Locke, the doctrine maintained that human nature endowed all humans with certain basic moral entitlements (such as the rights to life, liberty, and property), to which the manmade laws of society, both positive and customary, had to conform. These entitlements were called natural rights and assumed to possess five characteristics: they were discoverable by reason, itself a faculty of human nature; they existed before humans entered society; they applied to all humans by virtue of their being human; they were inalienable (i.e., could not be taken away); and they were restricted by the recognition of the rights of others only. As such, these rights limited the power of the society and its political and legal manifestation, the state. Respect for them was the foremost test for the legitimacy of political power.

The natural law doctrine had antecedents. Ancient ideas on rationalism, equality, and the restrained exercise of power formed its substratum. Despite its strong claim of immutability, however, many of its components, such as the exact catalog of moral principles or the source of authority for these principles, turned out to be rather flexible. Although temporarily fallen into eclipse because of the ascendancy of the sixteenth-century absolutist state, the natural law doctrine would be fostered by three developments initiated in that very period: with the Renaissance came an emphasis on individualism and secularism; the outcome of the religious struggles following the Reformation taught the necessity of tolerance; and the seventeenth-century scientific revolution marked the triumph of rationalism. These three developments reversed the philosophical priorities of the hierarchical medieval societies. Natural law gradually became associated with rights rather than duties and with individuals rather than groups.

The perception of the source from which these natural rights emanated also changed. Whereas Christianity had maintained that God was the ultimate source and political absolutism had invested the monarch with divine rights, the consent of the governed came to be seen as the final authority now. Individuals gave this consent in a social contract, which recognized that they possessed natural rights before entering society. Governments owed their origin to that contract, by which free and equal citizens agreed to entrust to a neutral sovereign body some of their nonnatural rights, to accept its authority and rules as long as it protected them, and to rebel against it if it did not. This became the basis for the rule of law and the separation of, and balance between, the legislative, executive, and judicial functions of government.

Although previous political theories paved the way and later ones expressed similar ideas, it was Locke's version that became iconic, especially outside England. In the age of Enlightenment, it exerted profound influence on the politicians behind the great democratic revolutions at the end of the eighteenth century. In the United States and France, natural rights, mainly of a political and civic character, were incorporated into the declarations of the revolutionaries. In 1789, natural rights were

transformed into the 'rights of man' (*droits de l'homme*). This marked the beginning of a slow process of codification of rights within the constitutions of most states and in international law that still has not ended.

This brief overview shows that, although many aspects of the human rights conception have an ancient pedigree, other crucial aspects have not. The gradual appearance of the concept was the result of a unique historic combination of particular series of events and philosophical thought reflecting upon them. The natural law doctrine itself eventually knew a curious fate: with unprovable tenets and with the possibility of abusive claims 'in the name of human nature,' it became overshadowed by the powerful state-centered thinking of the nineteenth century (as it had been in the sixteenth), but it survived. It was rehabilitated in a modest form during World War II. But the present approach sees human rights as an operationalization of the basic concept of human dignity rather than of human nature.

Absolute versus Relative Rights

The debate on moral versus positive rights was continued by liberal, conservative, and socialist critics of human rights, typically in such works as those of Jeremy Bentham (1748–1832), Edmund Burke (1729–1797), and Karl Marx (1818–1883). These critics argued against the abstract and absolute character of human rights and maintained that rights had to be connected to the society in which they historically were to be exercised. The liberal utilitarian Bentham believed only in the force of positive legislation. For him, natural rights were imaginary, 'nonsense upon stilts.' He feared that they were powerful rhetoric in the hands of rulers and a substitute for effective legislation. Unlike Bentham, the conservative Burke did not deny the existence of natural rights. He feared these rights, however, for reasons contrary to Bentham's: in the hands of the common people, natural rights would stimulate revolutionary sentiments and cause social upheaval leading to terror and to the destruction of the social fabric. Rights (and the duties linked to them) ought to be derived from the principles and values emanating from the particular traditions of a society. For the socialist Marx, the human rights doctrine was not radical enough. It left the inequalities generated by capitalism untouched (particularly private property) and therefore served the interests of the ruling bourgeois class. Because of these inequalities, the workers were unable to enjoy their rights fully, which therefore remained largely formal. As a class, the workers had a duty to create the conditions for social change by claiming collective social and economic rights with which to overturn the exploitative economic system. The new, egalitarian society to be established after the struggle had been successful, would be one without a state, laws, or rights.

These three critics did not stand alone, but their arguments gained a classic character and inspired powerful currents. Bentham's ideas gave impetus to the tradition of legal positivism. Ideas similar to Burke's would feed the romanticism and historicism of the nineteenth century to the extent that they also emphasized cultural identity and diversity. Marx's concerns activated the thinking about social and economic rights, heightened awareness of the need for social legislation, and influenced the 1917 Russian Revolution.

Men versus All Humans and Individuals versus Groups as Rights-Holders

Clearly, until long after its introduction, the concept of 'rights of man' covered only restricted categories of humans, usually male tax-paying citizens. The large majority of women, slaves, and foreigners were excluded. The struggle to include these categories into the ranks of rights-holders would lead to the final transformation of the concept into 'human rights.' As early as 1791, Olympe de Gouges campaigned for women's rights. With the movement against slavery, another group followed. Categories of individuals deemed particularly vulnerable (next to women and slaves, also children, aliens, refugees, prisoners, the disabled) eventually were protected by special regulations. Likewise, the difficult problem of how to realize group rights was introduced at an early stage in the human rights debate. Groups deemed vulnerable (minorities, colonized peoples, indigenous peoples) increasingly received special attention. Specific treaties drafted for national, ethnic, or religious minorities came into effect long before general treaties. The League of Nations, founded in 1919, did not formally recognize human rights but added pioneering treaties for minorities, refugees, and mandate territories.

From the movement to enlarge the concept of rights from selected human beings to all human beings, two further questions can be derived. The first of these is what the consequences are of the anthropocentric character of human rights, as it excludes other sentient beings. The other problem is whether past and future generations have human rights. As to past generations, it is difficult to ascribe rights to the dead, who are not human beings, but *past* human beings. Nevertheless, in this context, one could think of the duties of the living toward the dead concerning the dead body, the funeral, and the grave; concerning the will, the identity, and the heritage of the deceased; and concerning the images and texts about them. As to future generations, the preservation of the cultural heritage of humanity and of the natural environment is a chief concern as is the relationship between human rights and the human genome. As to future generations in relation to past generations, the accountability of successor governments for human rights violations committed by their precursors and their duty to investigate and prosecute these violations – with its corollary, the right to the truth – so as to combat impunity, became the focus of a new field of study: transitional justice (the full range of processes and mechanisms associated with a society's attempts to come to terms with the legacy of large-scale past abuses to ensure accountability, serve justice, and achieve reconciliation).

Domestic versus International Jurisdiction over Human Rights

Since 1800, two tendencies, one international, the other national, partly opposite, partly complementary, have dominated the debate over who was to supervise the protection of

human rights. A process of nationalization started when human rights were incorporated into the constitutions of growing numbers of countries. At the same time, human rights became part of the agenda of intergovernmental meetings, leading to the humanitarian interventions of the nineteenth century (continuing a tradition dating from the seventeenth) and the gradual incorporation of human rights into international law. The decisive historical moment for internationalization, however, came during World War II, when the link between human rights violations and war (hence, *a contrario*, the link between human rights protection and international peace and security) became clearly visible and, shortly after, when the Nazi and Japanese atrocities led to worldwide condemnation embodied in the international war crimes tribunals of Nuremberg and Tokyo. Although the United Nations only paid secondary attention to human rights in their 1945 Charter, this did not prevent work on an International Bill of Human Rights, consisting of a morally compelling but not legally binding Universal Declaration of Human Rights, adopted in 1948, and two International Covenants, one on civil and political rights and the other on economic, social, and cultural rights, both approved in 1966 and entered into force in 1976.

The idea of self-determination appealed to peoples under colonial rule or comparable alien subjugation and proved to be a crucial concept. It was a dangerous concept also because narrowing self-determination to only one of its possible interpretations – political independence, hence secession – was potentially explosive and because consensus was lacking as to who the rights-bearer ('a people') exactly was. Self-determination was promoted to a group right only in the 1966 covenants.

In the efforts to transform human rights into positive rights by making them enforceable in positive law, usually three stages are distinguished: standard-setting (codification of standards), ratification (making standards binding), and implementation (enforcing standards via sanctions). Seminal steps for enforcing standards were the elaboration of complaint mechanisms for state and nonstate actors (mainly since the 1970s), the appointment of a High Commissioner for Human Rights (1993), and the adoption of the Statute of an International Criminal Court with universal jurisdiction to prosecute alleged perpetrators (including heads of state and government) of genocide, crimes against humanity, war crimes committed in international and internal conflicts, and crimes of aggression (1998). Important preparatory work for these new devices was done by a coalition of nongovernmental organizations, the representatives of civil society. The elaboration of human rights institutions and mechanisms on a world scale was paralleled, and often preceded, by similar developments on a regional scale in Europe, America, Africa, and the Arab world.

In the midst of this evolution, the state was the key player. The cherished principles of the Westphalian world order, established in 1648, were national sovereignty and interstate equality. Their corollary, domestic jurisdiction, excluded interference from abroad in the internal affairs of the state. The vigorous doctrine of nationalism and successive waves of decolonization since the late-eighteenth century strengthened these principles. Paradoxically, recognition of national sovereignty made possible progress in international law with its core principle of interference in the internal affairs of states, for two reasons. First, states slowly realized that when they adopted human rights as the constitutional basis of the rule of law, they implicitly created a duty to protect them everywhere, including beyond their borders. Second, it became painfully obvious that the states charged with the protection of human rights very often were the main perpetrators of human rights violations. As a consequence, states eventually began to accept, although reluctantly, an international monitoring element that restricted their sovereign domestic power. The number of human rights campaigns and humanitarian interventions increased drastically in the 1990s, but their enabling conditions, forms (diplomatic, political, economic, or military), potential abuse, and effect were hotly disputed.

First- versus Second- versus Third-Generation Human Rights

As the list of human rights gradually expanded, analysts grouped them into 'generations.' First-generation rights, tied to the idea of liberty, were traditional or individual rights of a political and civic nature. They were characterized as negative rights ('freedoms from') because they favored government abstention. Second-generation rights, tied to the idea of equality, were modern or collective rights of an economic, social, or cultural nature. They were characterized as positive rights ('rights to') because they favored government intervention. Third-generation rights, tied to the idea of fraternity, were modern or collective rights of a global nature. They were characterized as solidarity rights and usually included the established right of self-determination and the newer rights to development, human security, peace, and democracy. The rights of indigenous peoples and the right to a life-sustaining environment frequently are added, but these also are listed as fourth-generation rights by some.

Each generation of rights emerged in a particular historical context. The first generation was the result of the so-called democratic revolutions of the late-eighteenth century. Increasing political emancipation and democratic participation in the next two centuries gave them further impetus. The second generation developed in the nineteenth century as the socialist tradition with its reformist and revolutionary strategies introduced ideas of welfare and social legislation to counter the exploitation of working classes. The third generation usually is associated with demands from colonial peoples, and after their independence, from the South for a worldwide redistribution of power and wealth, and with the delicate balance between global and local trends.

At the 1993 World Conference on Human Rights in Vienna, the second such conference ever and the first after the Cold War, the indivisibility of human rights was reaffirmed strongly. Even so, seven rights acquired a special status as they were the only ones stipulated by the 1966 covenants to be nonderogable, even in times of public emergency. They are the rights to life; to freedom of thought, conscience, and religion; to be recognized as a person before the law; and the prohibitions against torture and slavery, against imprisonment for nonfulfillment of contractual obligations, and against retroactive application of criminal laws.

The bewildering diversity of human rights nevertheless triggered much controversy on their compatibility and rank. Because all human rights were conceived as inalienable, they sometimes came into mutual conflict. A classic example of a conflict within the same generations of rights is the tension between free expression and privacy: both have to be balanced according to fair rules. But most conflicts occurred between, rather than within, generations of rights. Whereas first-generation rights assumed the character of universally enforceable standards, second- and third-generation rights were rather aspirations of the fulfillment which was utterly dependent on the creation and application of expensive state programs. Faced with all these demands, some states, mainly in the West, gave priority to first-generation rights, whereas others, mainly in the East and the South, campaigned, if not for the primacy, then at least for the equivalence of second- and third-generation rights to those of the first generation.

The strongest debates were held on whether political freedom should take priority over economic development or the reverse. During the Cold War (and even beyond), those defending the priority of political freedom (free minds) were accused of perpetuating inequality, those defending the priority of economic development (full bellies), of perpetuating dictatorial government. The hypothesis that political freedom or democracy has to be suspended until satisfactory levels of economic development are attained is contradicted by experience: in such cases, freedom usually is trampled underfoot, with no economic development attained after all. Unaccountable governments generally exacerbate economic and environmental crises. Moreover, how can a present suspension of freedom ever be conceived as a suitable preparation for its future protection? The reverse hypothesis, that economic development and political participation are interdependent, seems to have firmer ground: the exercise of civil and political rights is dependent to a certain degree on the fulfillment of economic and social rights (such as the rights to food and to education) and, in its turn, it is a requirement for citizens to participate actively in the economic development of the society. In short, there is no evidence for a conflict between political rights and economic performance. Research by the United Nations Development Program (UNDP) demonstrated that democracies are better than dictatorships in at least three crucial areas: managing conflicts; avoiding catastrophes and managing sudden downturns that threaten human survival; and helping spread the word about critical health issues.

This brings us to the major question of the relationship between human rights and political systems. Beginning with the Universal Declaration of Human Rights, all international human rights instruments advocate a democratic society as the best political system to protect human rights. In addition, the preamble of the Universal Declaration strongly condemns the dictatorships of the past. From this, the United Nations infer a simple definition of a democratic society: it is a society that recognizes and respects the human rights set forth in the Universal Declaration of Human Rights. This definition, simple as it seems, is strong because it combines the minimalist conception of democracy as the rule of the majority with a maximalist human rights-oriented application of the rule of law. Although, strictly speaking, no state in the world lives up to such an ideal definition, it points to the fact that a democracy is the best framework to facilitate proper conditions for the protection of human rights. In any case, human rights and democracies both emerged historically as the results of the 'democratic revolutions' of the late-eighteenth century.

Universality versus Relativity of Human Rights

The history of human rights expounded earlier, pointed to the Western roots of the human rights concept. Elements of the concept, such as some natural law principles, were available outside the West, but the combination of factors that led to its formulation was unique. As the West conquered the rest of the world, it introduced imperial dominance and violence. At the same time, however, its notions of nationalism, freedom, and human rights – developed initially for home consumption – fell on fertile ground around the globe: they proved able to transcend their particular roots and context. In the hands of colonized peoples, these notions echoed similar indigenous values and increasingly served to justly criticize Western exploitation in the language of the West itself. Thus, the claim of the universality of human rights has an anthropological basis, not a historical one: it is based on the worldwide appeal of a specific system of thought. In an unambiguous sense, this is logical because human dignity, as the foundational idea behind human rights, is a universal value with venerable traditions everywhere.

The critics of the universality of human rights remained skeptical. During the preparatory work on the 1948 Universal Declaration of Human Rights, leading U.S. anthropologists emphasized the cultural relativity of values and denounced the universalist pretensions of the intended declaration as cultural imperialism. Moreover, the historic critics of the universality of human rights, presented earlier, were succeeded by neo-Marxists, communitarians, and postmodernists. But the most influential group of critics was the vociferous ruling elites of some Asian and African countries. They challenged specific formulations of human rights, such as religion or marriage, and advocated, instead of universality, the principle of, for example, 'Asian values' or of domestic jurisdiction or of the primacy of second- and third-generation rights over first-generation rights. Remarkably, the victims of imprisonment, torture, and other violations in non-Western countries (among them many future elites of these countries), if they survived the prisons of dictators, found such criticism of the ruling elites unconvincing. They argued that denying universal human rights to citizens outside the West was itself a sign of cultural arrogance. One cannot deny progress in this regard: whereas the 1948 Universal Declaration of Human Rights was approved by a vote of 48 to 0 with 8 abstentions, at the 1993 Vienna Conference, 171 states unanimously reaffirmed the universality claim laid down in this declaration. This made the universality claim more representative and hence more solid.

Progress and Failure in the History of Human Rights

Recently, historian Bruce Mazlish defended the thesis that inhumanity breeds humanity. He argued that World War II and the Holocaust shocked the world to such a degree that, in

reaction, a human rights revolution was unleashed. This opinion can be called the *inhumanity thesis of human rights*. It is a strong thesis but not an unproblematic one.

If we want to test it, the first question is whether we can know anything at all about the moral nature of human beings. Are human beings good or evil? Many people, often inspired by religion, strongly believe in the intrinsic goodness of humans. In contrast, others, like Immanuel Kant, hold that human beings are antagonistic and bellicose. Still others, like the anthropologist Marshall Sahlins, think that goodness and badness are intertwined features and that the question of the good or evil nature of humans is a false question. If human beings cannot be called unambiguously either good or bad, how can we know whether inhumanity has increased or decreased in the course of history? In absolute terms, the case for an overall increase of inhumanity is quite defensible. Population growth on earth and the increasing efficiency of repressive technologies make this probable. Our perception, however, may be misled: we may overestimate the present absolute level of inhumanity because of our lack of knowledge of inhumanity in the past. Alternatively, we may underestimate the present level because we are too impressed by the recently expanding human rights awareness. In relative terms, the question is different: given that an equal amount of inhumanity probably leads to greater absolute destruction in modern times, were past societies more repressive or more humane toward their citizens than those of the twenty-first century? When we look at the number of victims of human rights catastrophes as a percentage of the total population, it is not certain at all, as many think, that present-day rates are higher than those of the past. Peter Singer has argued that in many tribal societies, despite the absence of machine guns and high explosives, the percentage of the population killed annually in warfare far exceeded that of any modern society. A probable absolute increase of inhumanity in history, then, does not imply that humankind is more barbarous now than it was in the past, nor that it is less. If anything, it seems likely that, in relative terms, levels of inhumanity are fluctuating or even possibly in decline.

If the level of inhumanity is not necessarily on the rise, why did large-scale inhumanity not trigger a human rights regime before the eighteenth century? We can only speculate that, in the further past, massive violence was perceived to belong to the *condition humaine*. At the same time, attention to the fate of victims of crime has an impressive pedigree: everywhere, religious and ethical systems have preached principles of humanity throughout history (although these systems often defined humanity in a limiting sense). We are forced to conclude, however, that the accumulative force of humanitarian attempts in the further past apparently did not pass a critical threshold.

Another question concerns the watershed in human rights thought as it first appeared in the United States and France in the late-eighteenth century. According to Lynn Hunt, one of the factors explaining this human rights takeoff was the appearance around 1760 of a new genre of novels – epistolary novels – which made their readers sensitive to new experiences and enhanced in them the empathy and sympathy necessary to imagine new political conceptions, such as equality and human rights. Another equally strong factor was the development of new views of individual autonomy, which brought more respect for the body, making the practice of torture suddenly look unacceptable. The first factor, the influence of epistolary novels, seems implausible. It cannot be doubted that reading these hugely successful novels enhanced sympathy. But that is not enough to foster human rights. The sympathy aroused when reading epistolary novels is particularizing – directed at the protagonists of the novel – and not universalizing: it often is accompanied by a rejection of all those who are their adversaries. Thus, the transfer of sympathy is limited, and it stops shortly after the novel is read. No inclusive sympathy is reached in this way. There is additional support for this objection: nearly all of the tremendously popular protagonists of these novels were women, but women's rights were about the last category of rights to be realized. In addition, one of the foremost human rights campaigners, Mary Wollstonecraft, was skeptical about this novel reading.

In contrast, the second factor, the general outburst of revulsion against torture, is plausible. The intolerable character of ill-treatment led to the formulation of rights to protect physical integrity. It begs the question, however, of why torture generally was not seen as repulsive *before* 1760. It therefore is clear that, in addition to the torture factor, other conditions were necessary to spread the new insights. Hunt stressed that philosophers and legal scholars writing about human rights were read widely on both sides of the ocean. She also emphasized the practical advantages of thinking in universal terms: in America, the English colonies did not aim at reform but at independence, which made reference to a universal set of values attractive and necessary; in France, the new principles were cast in the language of universality and so opened vast horizons of applicability hitherto unthought-of. This is not to say that the newly formulated rights were enforced immediately. Trials of major perpetrators of human rights violations, for example, had not yet taken place. In short, the inhumanity thesis holds only partially for the human rights takeoff of 1760–1800. The question of why some relatively successful concept of humanity arose in France and the United States in the eighteenth century, but not elsewhere, merits more attention.

The next question is intriguing. After so promising a start around 1760–1800, why did the human rights idea fall into eclipse between 1800 and 1940? It implies another question: did the idea *really* become eclipsed after 1800? Some developments testify to the continuation of the élan during these 140 years. One could point to the strength of the movement for the abolition of slavery, the Geneva Conventions, the gradual development of customary rules of international humanitarian law, and the Hague Conventions. These developments of the nineteenth century were followed by myriad important if relatively modest human rights initiatives in the interwar period, including those of the League of Nations. Although research may further reveal that the eclipse was not as total as it might look at first, it seems unlikely that this period will prove an uninterrupted triumph of human rights. The human rights idea was attacked by conservatives, liberals, and socialists. Powerful currents of defensive nationalism, imperialism, and racism in the nineteenth century, and scores of dictatorships appearing in the

twentieth century, discouraged thoughts about universal human rights before 1940.

For our purposes, it is noteworthy that an initiative such as the establishment of the Red Cross was propelled by a war: the 1859 Battle of Solferino. The Red Cross would become the official custodian of the Geneva Conventions. As this still is the most important instrument for humanitarian action in times of war, the Solferino connection adds considerable credibility to the inhumanity thesis. In contrast, World War I yields an ambiguous picture. On the one hand, although it saw a genocide (the Armenian genocide), an attempt to try its perpetrators failed. On the other hand, one of its results was the League of Nations, an initiative meant to stimulate international cooperation. It seems that none of the steps taken in the period between 1800 and 1940 was decisive.

The next question is whether the inhumanity of war and genocide really triggered the human rights revival of 1940–1948, as was postulated by Mazlish. The factors 'war' and 'genocide' played different roles. A total war of aggression was being visibly prepared by Nazi Germany from at least 1938. H.G. Wells and others mounted a human rights campaign immediately after the start of the war in September 1939. Some of Wells's ideas were picked up by Franklin Roosevelt in his Four Freedoms speech in 1941. It is still not clear, however, whether the main document of the new epoch, the United Nations Charter (1945), played a catalyst role in the campaign. Some emphasize that the mere mention of human rights in the Charter was sufficient to establish a Human Rights Commission, whose first assignment was to draft the Universal Declaration of Human Rights.

The other factor, genocide, was more ambiguous. From the summer of 1942, it gradually dawned upon the Allies that the Nazis were performing a large-scale extermination campaign, but the truth in its full brutality became generally visible only in the last months of the war. This was sufficient to unchain the process to draft the 1948 Genocide Convention, which represented a serious breach of the sacred principle of nonintervention in domestic affairs of states. Strangely enough, however, there was little connection between the debates about the Genocide Convention and those about the Universal Declaration, although they were held simultaneously, and it therefore is not clear whether the Holocaust was incessantly on the minds of the drafters of the Universal Declaration. We must realize how uncertain the semantic impact of the term 'genocide' still was between 1945 and 1948: this new concept was to conquer the minds of the masses only slowly. The Nazi genocide, when it was on the minds of the drafters of the Universal Declaration, was immersed in a more general aversion to Nazi barbarity. Even if such awareness of Nazi barbarity was omnipresent, the idea that the worst part of that barbarity constituted a unique crime called 'genocide' only slowly emerged in wider circles.

Recently, the historian Samuel Moyn has challenged the view of the deep roots of human rights. For him, human rights have been really successful only since 1977 when they finally left their United Nations quarantine and became embedded in a lasting mass movement. That mass movement was the result of the emergence of Helsinki groups and other human rights organizations in Eastern Europe and the Union of Soviet Socialist Republics, the incorporation of human rights into the politics of President Carter in 1977, and the conferment of the Nobel Peace Prize on the grassroots organization Amnesty International later that year. These factors coincided with structural developments, such as the collapse of the credibility of the geopolitical rhetoric of the Cold War and the postcolonial disillusionment with revolutionary political utopias. According to Moyn, human rights emerged as a minimalist and practical utopia, with moral rather than political overtones. Moyn also argued that the belated success of human rights was accompanied by the invention of a longstanding tradition starting in 1760, whereas, in reality, the survival of the idea of human rights was but a story of contingencies.

Moyn's analysis is convincing with two important caveats. First, his debunking of human rights antecedents before 1977 depends on a particular appreciation of historical rhythms. For example, one of the most notable developments, the incorporation of human rights notions into most of the world's constitutions well before the 1970s, is called 'a fashion' by Moyn. There was not only coincidence after coincidence, in myriad ways there was also an accumulated pressure not to let the human rights idea die. From 1945 to 1948, attention to human rights was huge in comparison to anything that had happened on that front before 1945, but it was modest in comparison to anything that was to happen after 1977. In short, the breakthrough of 1977 was unthinkable without this preparatory work. Second, like Mazlish, Moyn underestimated the strength of humanitarianism, largely because he equated it with philanthropy (*social* humanitarianism). Despite some overlap, *legal* humanitarianism is very different from philanthropy. The Red Cross not only crafted the subtle edifice of the Geneva Conventions but also played a substantial role in the development of several human rights (such as the right to the truth) and of court statutes (such as the 1998 statute of the International Criminal Court).

It is clear from these factors that inhumanity did not play a major role in the breakthrough of 1977. The wars and genocides of the 1960s and 1970s surely provoked indignation, but they had no lasting resonance among human rights activists. Still, one inhumanity-related factor did play a role. Outraged by the repression of Latin American dictatorships in the 1970s, Amnesty International launched its antitorture campaign in 1973. This campaign met with overwhelming approval and perhaps became the major key to Amnesty's success. Here, as in the 1760s, the general repugnance against torture was a powerful stimulus.

Juridical globalization from 1998 was an important next step. In contrast to the boost of 1977, this recent wave of global justice *does* have a direct connection with war and genocide: the wars in the former Yugoslavia and the ethnic cleansing and genocide there and in Rwanda led to the establishment of international tribunals, which formed the laboratory for the International Criminal Court and accelerated the process of approval of the latter's statute in 1998. This indicates at least modest progress.

Some, however, insist that all these results are meager. Where some see progress, these critics see regression or stagnation. This skepticism is not unreasonable. Indeed, those defending the judgment of recent progress in human rights may be misled: *any* progress in this area is impressive when the start is recent and the level of departure low. The judgment of recent failure of human rights, in its turn, has to meet several empirical objections also. First, the imperfect application of the concept of human rights in everyday reality does not

necessarily discredit the concept itself. Second, among the growing number of planetary *lieux de mémoire,* which stimulate global awareness, some of the strongest belong to the class of inhumanities: the Holocaust, Hiroshima, and 11 September are examples. Third, even skeptics have to admit that a world without a Universal Declaration is worse off than one with such a declaration. The Geneva Conventions are ratified by all countries in the world. There is also the idea of genocide. It was given shape in a convention in 1948, but the first sentence ever for genocide was handed down in 1998: half a century later. Since then, convictions for genocide have multiplied rapidly. Last but not least, the political regime best suited to protect human rights – democracy – has made considerable progress over the past decades. The UNDP recently showed that the share of democracies increased from less than a third of countries in the early 1970s to three-fifths in 2008. At the same time, however, the reported levels of human rights violations have remained virtually unchanged globally between roughly the same decades. It thus seems that the rise of democracy, casting doubt on the judgment of recent failure, was matched by stagnation rather than a rise in human rights protection, casting doubt on the judgment of recent success. Both judgments can be the product of ahistorical myopia. It further shows that even if democracy is the regime most favorable to human rights, progress is not to be taken for granted.

It is now possible to evaluate the inhumanity thesis. The relationship between inhumanity and humanity is not a necessary one. There were many instances in which inhumanity only gave birth to more inhumanity and to new cycles of violence. Conversely, progress in human rights thought often was unrelated to any act of inhumanity. Proof for the causal role of the inhumanity factor was weakest during the most important breakthrough, the one of 1977. At several moments in history, however, inhumanity *did* propel humanism. And it was not always the worst inhumanities that provoked a response in terms of human rights. Even the awareness of the risks of inhumanity often was sufficient. The unbearability of repetition probably played a role as well: it may explain why the human rights response was stronger after 1945 than after 1918. This is hopeful. For if the inhumanity thesis were necessarily true, we would need more human rights catastrophes to book more human rights progress. And that would be a self-defeating paradox. But progress in human rights is not given, it is fought for. As Kant wrote, "Nothing entirely straight can be fashioned from the crooked wood of which humankind is made."

Human Rights: Legal Aspects

Jonathan Klaaren, University of the Witwatersrand, Johannesburg, South Africa

Abstract

Human rights can be viewed from legal and sociolegal perspectives. From a legal perspective, human rights are the rights derived from the Universal Declaration of Human Rights, the International Covenant on Economic, Social and Cultural Rights, and the International Covenant on Civil and Political Rights and other human rights instruments; they are enforced on both international and domestic levels. Sociolegal perspectives, embedded within the disciplines of history, sociology, anthropology, and international relations, instruct that human rights are not constrained only by law; they have their own history, sociology, social life, and transnational activist networks. The issue may be posed whether the field of human rights has moved beyond a topic of interdisciplinary research to become a distinct discipline.

Introduction

An article entitled 'Human Rights: Legal and Sociolegal Perspectives' must designate its subject matter. For this purpose, the term 'human rights' is used here to identify primarily universal or international human rights rather than rights within nation-states. Thus, by human rights, this article understands the international human rights regime rather than national ones. The two remits overlap but are distinct (Henkin, 1979). International human rights are often identified and given legal weightage by a series of international human rights treaties and declarations adopted by the United Nations (UN) (or other international organizations) in the two decades following the end of the Second World War beginning with the Universal Declaration of Human Rights (Sieghart, 1983).

It is also necessary to be clear about the perspectives from which this subject will be approached. The article is written from both the legal and the sociolegal perspective. It thus surveys a range of perspectives including but not limited to those within the discipline of law. Other articles in this encyclopedia address matters of legal doctrine related to human rights (see cross-references above).

Human rights almost need no introduction in an encyclopedic work, as their significance is widely understood. As the pioneering American law professor Louis Henkin wrote, we live in 'the age of rights' (Henkin, 1990): Many if not most of the significant issues of our day are framed in and resolved within a human rights frame of reference (Sarat and Kearns, 2001: p. 2). With significant variations across the diverse societies of the globe, this has been the case, broadly speaking, since the end of the Second World War (Minow, 2002). Further, much of the modernizing and progressive energy of social-change advocates intending to make the world a better place is often expressed in human rights terms. Indeed, this has been the case with the drive to ensure equality within and among nations, as well as with the drive to end poverty, as we have begun to recognize a human right to development (Alston, 1988). Indeed, as the world continues to globalize yet does so in new ways, the doctrine of human rights as distinct from national or constitutional rights takes on new significance. New constitutions and innovative doctrines in international law draw their social significance and legitimacy partially but increasingly from human rights.

A work of survey must start and end its mapping somewhere. In its main body, this article will first detail a legal perspective on human rights. This presentation of significant human rights instruments, institutions, and legal issues is largely internal to the human rights field and to the legal discipline. Second, the article turns to a survey of four sociolegal (interdisciplinary) perspectives on human rights, addressing works from history, sociology, anthropology, and international relations. The article concludes with a brief reflection on the development of human rights as a perspective (an intellectual discipline) in its own right.

Human Rights: A Legal Perspective

Within the discipline of law, there are a myriad of approaches to human rights. The aim here is to identify the key conceptual distinctions made, and institutions resourced, in order to provide a legal perspective on human rights.

One should start with the legal delineation and source of universal human rights. Popular usage conflates as human rights several fields of law that are often kept conceptually distinct within the discipline of law: international human rights law, international criminal law (Slye and Van Schaak, 2009; Van Schaak and Slye, 2010), international humanitarian law (Sassioli et al., 1999), and international refugee law (Goodwin Gill and McAdam, 1996; Hathaway, 2005). In practice, however, specific human rights issues may be addressed from legal perspectives based in more than one of these fields. Moreover, emerging issues (e.g., the development of international criminal tribunals and the field of transitional justice) often arise at the intersection of one or more of these fields.

International human rights law scholars tend to distinguish between international instruments under the auspices of the UN, on the one hand, and regional instruments of international law on the other. The Convention on the Elimination of All Forms of Discrimination Against Women, which was adopted by the UN General Assembly in 1979, is an example of the former, as is the African Charter on Human and Peoples' Rights, agreed to by the Organization of African Unity in 1986. Other regions adopting regional instruments include Europe (the European Convention for the Protection of Human Rights

and Fundamental Freedoms) and the Americas (the American Convention on Human Rights).

A further distinction within international human rights law is that between civil and political rights on the one hand and socioeconomic rights on the other. This distinction builds on the existence of three separate UN human rights instruments: the Universal Declaration of Human Rights (adopted in 1948), the International Covenant on Economic, Social and Cultural Rights (1966), and the International Covenant on Civil and Political Rights (1966). Recent scholarship contests this distinction and stresses the historical and conceptual indivisibility and interrelatedness of all forms of human rights (Kabasakal Arat, 2006; Whelan and Donnelly, 2007).

From a legal perspective, human rights occasion what one might call the ideal of legal compliance with human rights. In this ideal, human rights are identified and agreed to by the UN (or a regional body of states) in the form of human rights treaties. These legally binding treaties are then enforced in three possible ways: through actions among the states themselves, through actions of agencies of the international community of states, or through domestic actions of the states ratifying and incorporating those treaties. In this ideal, the specific mode of enforcement does not assume any great significance but the fact of compliance – of adherence to human rights – does matter.

Given this ideal of legal compliance with human rights, one might identify two broad levels of formal enforcement of human rights: the international level, understood to include the community of states as well as institutions such as international courts and tribunals, and the domestic level, understood to include constitutions as well as domestic institutions such as courts and human rights commissions. Some human rights legal scholars are of the opinion that the impact of human rights treaties has been more significant through their use at the national level than through the supervisory measures they provide for, such as state reporting and individual complaints, at international levels (Heyns and Viljoen, 2001). Indeed, international human rights legal scholars have paid careful attention to whether international human rights treaties make a difference (Hathaway, 2002; Goodman and Jinks, 2003, 2004; Halliday and Schmidt, 2004).

At the international level, states can and do pressure each other regarding compliance with international human rights law. For instance, the signing of the Helsinki Final Act of 1975 established human rights as a norm ostensibly binding on all states of Europe. Following 1975, states could legitimately call each other to account on human rights issues, citing the Final Act (Thomas, 1999). More recently, over the past two decades, states have established a number of independent international tribunals with powers and procedures akin to those of domestic courts (see e.g., http://jura.ku.dk/icourts/icourtfinder/). States may have established these institutions in order to increase their own credibility in a number of multilateral settings (Helfer and Slaughter, 2005, 1997).

At the domestic level, the primary institutions seen to be implementing human rights law are domestic constitutions, courts, and human rights commissions. Thus some human rights scholars and organizations have examined the impact of the evolution of the international human rights regime on national bills of rights, arguing that the development of the regime has transformed many of the debates around domestic bills of rights (Alston, 1999). Others have argued for the articulation of a common law basis for international human rights law in order to bypass the question of the status of human rights law as 'incorporated' or 'unincorporated' (see below) in English courts (Hunt, 1997), while still others have argued that the initial performance of most African human rights commissions has been disappointing (Human Rights Watch, 2001).

Along with attention to these two levels of formal enforcement, human rights legal scholars also pay attention to questions of culture (including the issue of cultural relativism) (An'Naim, 1995) and of civil society organizing and advocating for human rights concerns (Welch, 1995).

Deeply intertwined – at least from a legal perspective – with the enforcement process are a number of issues and questions of doctrinal law. For example: (1) what rules govern the interpretation of international human rights treaties? (2) is a particular human rights instrument a treaty (and thus binding at international law) or not? (3) has the treaty been ratified by sufficient numbers of states to have entered into force? (4) has a particular state ratified the treaty and, if so, when? (5) did a particular state make any reservations (excluding or modifying its effect) to a human rights treaty? (6) what is the domestic legal effect of the human rights instrument? (7) has the state temporarily derogated from or suspended the human rights instrument? and (8) has the potential enforcement of a human rights matter exhausted domestic remedies? (Martin et al., 1997). Much of human rights law, from the point of view of its practitioners is taken up in addressing and resolving these doctrinal legal questions.

Human Rights: Four Sociolegal Perspectives

Consistent with their claimed universal nature, human rights have overlapped with nearly every discipline and significant community of practice. For instance, political scientists have long been interested in the dynamics and power of human rights, and scholars of human rights have often been its powerful practitioners and politicians. An example of the latter is Michael Ignatieff, serving as the Leader of the Official Opposition in Canada for several years. Broadly speaking, disciplines can offer both internal and external perspectives on human rights. The four disciplines surveyed below – history, sociology, anthropology, and international relations/politics – arguably go a step beyond and offer a perspective that may be constitutive of the discipline of human rights itself.

History and Human Rights

As a relatively recent development, historians have begun to explore the histories of human rights. For instance, a timely and recent cultural and intellectual history of human rights traces the roots of the concept to the rejection of the practice of torture as a means for finding the truth (Hunt, 2007). In a different vein, Moyn has argued that in the 1970s "the moral world of Westerners shifted, opening a space for the sort of utopianism that coalesced in an international human rights movement that had never existed before" (2010: p. 1). First, other histories narrow their focus and probe the origins of human

rights within a particular national jurisdiction, such as in South Africa (Dubow, 2012). The study of human rights takes such scholars into a particular specialist area of law – human rights – but human rights arguably presents no greater methodological challenge than the one faced by historians of business studying the development of the railroad industry in the nineteenth century. For historians, the entire field of social activity is available as data and evidence. Still, these histories of human rights have been influenced by two hallmarks of a sociolegal perspective: first the attention to the 'gap' between the law 'on the books' and the law 'on the ground' and, second, the attention to the variety of ways in which law and the variety of interpretations of law interrelate and influence each other.

Sociology and Human Rights

While the recent attention to human rights within sociology has picked up from the mid-2000s, there has been earlier attention. One strand of such attention draws upon the key normative concerns of the discipline. Turner, for instance, made an argument for a sociology of human rights that would serve as a substitute for national citizenships, which he saw as inherently limited (Turner, 1993). Sociologists have continued to work within this universalizing moral and normative vein (Soysal, 1994; Turner, 2010; Friesen, 2011a). Friesen has argued that "A human rights approach offers an opportunity to unite apparently disparate concentrations of the discipline – such as race, class, gender, sexual orientation – into a larger framework which analyzes equality and fairness on a *human* scale" (Friesen, 2011b). The sociological perspective can also bring two important correctives to practitioners of all types working in the field of human rights: a certain degree of reflexivity about the use of human rights tools as well as a way to exhibit "a reliance on legal institutions that remains aware of their limits and their own direction" (Hagan and Levi, 2007: p. 373).

Anthropology and Human Rights

Anthropologists have recently realized that they have much to offer to the field of human rights. Anthropologists emphasize what Richard Wilson terms 'fully documenting the social life of rights,' by which he means "the social forms that coalesce in and around formal rights practices and formulations, and which are usually hidden in the penumbra of the official political process" (Wilson, 2006: p. 78). For instance, one anthropological strand of productive research has been concerned with human rights and the police (Hornberger, 2011, 2010). Anthropologists have also offered the insight that human rights thinking itself originates within a specific culture that has often resided within and been symbiotic with American institutions, including notably American law schools (Riles, 2006).

One concept key to human rights that can be emphasized from the discipline of anthropology is what Mark Goodale, working with an ethnographic and critical approach to human rights, has termed 'betweenness.' Goodale and Merry describe "the locations where human rights discourse emerges in practice as 'between' the global and the local" (Goodale, 2007: p. 22; Goodale and Merry, 2007). For them, "betweenness is meant to express the ways in which human rights discourse unfolds ambiguously, without a clear spatial referent, in part through transnational networks, but also, equally important, through the projection of the moral and legal imagination by social actors whose precise locations … within these networks are (for them) practically irrelevant" (Goodale and Merry, 2007).

International Relations/Politics and Human Rights

International relations/politics has taken on the study of human rights as one of its core topics of research. Perhaps the classic theme in this field is to ask the question whether the norms of international human rights have had any effect on domestic governments (e.g., Risse et al., 1999). The answer, by and large, is often positive although usually not determinative or conclusive. An additional theme is to examine the working of the human rights movement. Here, one work that has achieved great prominence and influence is Keck and Sikkink (1998). Keck and Sikkink introduce network analysis to the study of human rights activists and work with the concept of transnational activist networks. In their view, human rights networks are "vehicles for communicative and political exchange, with the potential for mutual transformation of participants" (1998: p. 214).

Conclusion: A Reflection on Human Rights as a Distinct Discipline

This section asks the question whether the field of human rights is, or is becoming its own discipline, in the sense of an intellectual school of thought (which often bear a parallel to institutional developments in centers of knowledge production such as universities).

There is clearly a tradition of human rights scholarship that spans both a significant time period and a range of perspectives. For instance, one can track the development from the formative and field building work of Jack Donnelly (2013) to the more critical approach of Makau wa Mutua (1996, 2001, 2002). The former was deeply committed to the universal impulse of the human rights field and the latter, while departing from and using that assumption as a starting point, is nonetheless fundamentally critical of earlier work.

Moreover, approaches based within the human rights field have shown their power to reveal insights. For instance, one approach that might be understood to be located within a distinct human rights field is that of Martha Minow. She studied a range of responses to human rights violations, genocide, and other instances of mass violence. In her view, law can provide a repertoire of such responses (1998). This focus has led Minow to identify an institutional characteristic of responses to human rights violations that can be understood to run parallel to the betweenness concept identified at the heart of human rights practice by Goodale and Merry. In Minow's view (2002: p. 59), "[t]he advocates of human rights have generated innovative institutions and practices, yet the successive and multiple nature of these innovations can contribute to the sense that human rights are merely ideal aspirations and, in practice,

insecure. Yet this tradition of institutional innovation may be the most significant legacy of the human rights movement."

Furthermore, analyses based within the human rights field have had significant impact in the world of the academe as well as in the policy world. For instance, as influential a thinker as the philosopher and economist (not to mention his being a winner of the Nobel Prize) Amartya Sen has worked extensively within the field of human rights (1997, 2004). This impact has also been in the form of new knowledge creation. The field of transitional justice saw great growth as a specialized and potentially distinct field of practice and knowledge in the 1990s and 2000s. However, transitional justice seems not to have achieved status on its own as a discipline. Instead, the growth of the transitional justice field (which may best be understood to be included within that of human rights) seems rather to indicate the depth and diversity of topics within the human rights discipline.

An alternative to seeing human rights as a distinct discipline is to see it as an interdisciplinary field of study. Here a parallel to sociolegal studies itself may be illustrative. Sociolegal scholars have also asked whether their corner of the academy is a distinct discipline. By and large, the answer has been in the negative. It would seem that human rights rather than sociolegal studies has a better claim to (and chance for) distinct academic discipline status. Indeed, if the study of human rights is not a distinct field, then human rights is at least a topic for interdisciplinary work (Freeman, 2011). This article thus far might be seen as an example of an interdisciplinary approach toward a new and significant research topic. Work such as the recent history of human rights (Moyn, 2010) demonstrates a step toward such a development.

Abstract

The term Human Sciences is primarily a French usage, but it refers back to a much deeper tradition in the literature claiming that works of the spirit and human experience cannot be reduced to the realm of causal science, and require different methods. Following Kant, much of this discussion has focused on the problem of the conceptual formation of human experience. Methodologically, discussion has shifted back and forth between an emphasis on concepts, on experience, and external facts. Foucault and Bourdieu extended the critical possibilities of the notion of misrecognition to ally the human sciences with critique.

The social sciences have been known by many names, including the moral sciences, the *Geisteswissenschaften*, the behavioral sciences, and the 'sciences of man.' Each of these names conveys a particular philosophy or methodological ideology, and typically includes or excludes some other discipline, such as psychology or law, and emphasizes some disciplines, such as linguistics, as especially exemplary. But the boundary lines and differences are not very precise, and they are evident more in the history of methodological disputes than in actual usage and administrative practice.

The *Sciences Humaine*, or Human Sciences, is a term of French origin. It appears in Francophone settings in numerous official and academic contexts, for example, in the name of the *L'Institut des Sciences Humaines et Sociales*, part of the *Center National de la Recherche Scientifique*. Part of the mission of the former institute is the promotion of interdisciplinary work, and the term 'human sciences' carries a suggestion of interdisciplinarity. The name also appears in the designation of faculties, in such combinations as Philosophy and the Human Sciences, Letters and the Human Sciences, Law and the Human Sciences, and Human and Social Sciences. The term *Sciences de l'Homme* overlaps this usage, but implies both a narrower definition, limited to the traditional social sciences, and a broader one, in that it implies nothing about methodology, and can be stretched to include human biology and the neurosciences. Often the term is used to encompass all of 'sciences' of the human, including history, geography, economics, law, political science, administrative science, educational science, linguistics, psychology, and the traditional social sciences. It is occasionally extended to include the humanities in general, as well as theology.

As the label 'Human and Social Sciences' suggests, however, it is often used as a means of distinguishing the approach from at least some of the social sciences, or some aspects of the social sciences. The American National Endowment for the Humanities uses the phrase "those aspects of social sciences which have humanistic content and employ humanistic methods," which captures this distinction. But in English usage, the term science is used as a way of distinguishing its methods from those of the humanities. In Continental and especially German usage, the term 'science' (*Wissenschaft*) is applied to any form of organized knowledge including those using the methods of the humanities. The journal *History of the Human Sciences* includes "traditional humanistic studies as well as the social sciences," and "publishes wide-ranging material in the fields of sociology, psychology, political sciences, the history and philosophy of science, anthropology, classical studies and literary theory."

Despite this amorphousness, the term designates something coherent: a more or less common approach opposed to the 'moral sciences' of J.S. Mill and the positivism of Auguste Comte and to their scientistic heirs. The central philosophical argument for this opposition was the irreducibility of something (meaning, intention, subjective experience, language, culture, historical individuals, etc.) to science, or to any law-like or causal analysis. In addition, it was claimed that there was knowledge, or access, to these irreducible things through other means, such as understanding, introspection, or empathy, reflexivity, or through hermeneutical or phenomenological analysis, or through a scientific analysis of a different, structural, kind, of language, artifacts, or cultural objects, practices, and patterns of human conduct.

The Philosophical Background

In a late interview, Michel Foucault, who was not only an influential figure in, but also an historian and architect of the human sciences, commented that "we are all Neo-Kantians" (Foucault, 1994: vol. 1, 546; quoted in Han, 2002: 3). This is true, in very complex but important ways, and applies more generally to much of what goes under the label 'Human Sciences.' To understand his comment it is necessary to explain Kantianism and neo-Kantianism and their persistent importance for the Human Sciences.

The Kantian heritage runs through the history of the human sciences in two basic ways. The first is the obvious one: for Kant the human world was the world of free will and spirit, guided by the moral law, in contrast to the physical world, governed by deterministic law. The second is related to the Kantian dictum that we can know and understand only what we make, and not the world as it is: "we have complete insight only into that which we can make ourselves and according to our own concepts" (*Critique of Judgment*, §68; quoted in Beiser, 2006: 13). But the path from Kant is anything but simple. The German idealists radicalized and with Hegel historicized these ideas, and they were taken up in misunderstood but

fertile ways by other thinkers, especially in France (Schmaus, 2004), and blended, not to say entangled, with other ideas.

Among the other issues that early nineteenth century discussions were entangled with were theological ones, especially issues over Biblical interpretation. These led to the notion of hermeneutics as a distinct method, not only for the interpretation of texts but for human understanding. The idea of understanding as a distinct mode or kind of knowledge specific to the study of humans led to a large discussion of the distinction between explanation and understanding, and of their possible relations about the nature of man.

The theological entanglements were connected with the traditional idea that the Christian message could not be understood except through faith: that only an act of faith opened one to the true meaning of Christianity and experience of Christ. The sharpness of this discussion was a result of the growing conflict between science and theology: theologians worked hard to find a preserve of modes of thought, belief, and knowledge that science could be excluded from. Inner knowledge, inner experience, was made central to the experience of religion, and thus to one's humanity.

The German Idealists who followed Kant and radicalized him developed various forms of what Arthur Schopenhauer was to call, in the title of his major work, *The World as Will and Representation* (2010), by giving a large role to Will or construction in their accounts of and extending these notions to the social and political world, especially to the nation as an object of thought. Schopenhauer denied the subject-object distinction, claiming that our only knowledge was of ideas, or representations. Johann Gottlieb Fichte (2005), similarly, rejected the Kantian idea of the unknowable thing itself, and instead focused on subjectivity as the source of our representations and therefore all that we can know. With Fichte we get the idea that consciousness is a social phenomenon, and that consciousness of other rational individuals precedes the 'call' which brings out individual consciousness. This is the beginning of the idea of intersubjectivity. But with Fichte we also see the development of some more sinister notions of national mentalities that are not unrelated to his philosophy,

The idea of a *Volksgeist* is one of the many collectivist notions of mental life that figures in the early history of the human sciences. This concept had a special historical importance. It was associated with the aristocrat and professor of law Friedrich Carl von Savigny, who argued that the specific form of law of a state arose from the historically rooted spirit of the people. Von Savigny, by taking up a career as a professor, raised the status of the German universities, contributing to the process that led them in the late nineteenth century to be the world standard. Ideas with collectivist character, such as the idea of a shared *Weltanschauung* (world view), mystical ideas about community and about the nation as a community of fate, as well as medievalist nostalgia for organically unified societies all went together and merged in an anti-individualist, anti-liberal, anti-economistic, and anti-English mélange, which was associated with German national identity.

These ideas were not originally associated with Kantianism. Indeed Johann Gottfried von Herder, Kant's student, developed his own ideas of *Volk*-thought in opposition to Kantianism. But the affinities between German Idealism in the period between Kant and Hegel and collectivist ideas were strong. Nevertheless, the picture is not simple: there was German liberalism and individualism that Herder, Wilhelm von Humboldt, Rudolph Gneist, and others also promoted, which typically connected the idea of individual development and freedom with the idea of national development and freedom. Reconciling the two kinds of freedom was a characteristic concern of these thinkers, and of Hegelians, one often resolved by notions of the mystical harmony between the two.

The relationship between German nationalism and ideas about the sciences of the human was to persist as the methodological discussions developed. The earliest and most intense of these methodological discussions preceded the idea of a human 'science.' They were concerned with historical knowledge, which raised the question of the individual in acute form. German historicism is usually thought to begin with the notion of the distinct individual developing according to its own being, a doctrine that applied to *Kollektivgebilde* or collective beings such as nations or even shared ideas as well as to individuals (Bos, 2010: 209). If each individual had his or her own principle of development, it was necessary for the historian to respect this: to exhibit the specific and unique character of the individual in time.

This had methodological implications that immediately distinguished history from generalizing sciences. Humboldt developed these thoughts by arguing that history itself did not have an aim or *telos*. This argument was taken up in the middle of the century by Johann Gustav Droysen, specifically against Hegelian accounts of history. For Droysen, the father of historical hermenuetics, objectivity in the sense of Leopold von Ranke's history as it actually happened was overrated, and Hegelian history in terms of the absolute idea was delusional. In a famous statement, he said:

> I want to appear to have nothing more – but also nothing less – than the relative truth of the standpoint bequeathed to me by my fatherland, and political and religious convictions, my earnest study. (Quoted in Maclean, 1982: 361)

This self-confessed reflexive relativism contained, among other things, a sense of the relativity of historical standpoints, the relativity imposed by the need to speak to present audiences. For Droysen this went with a higher valuation of understanding: he is the father of *Verstehen* as a goal of historical inquiry. Interpersonal understanding is both the basis of social existence and of historical inquiry (Maclean, 1982: 359).

The Neo-Kantians

With this we have the fundamental elements of the human sciences, which cohere with Wilhelm Dilthey and the neo-Kantians. The relations between Dilthey and the neo-Kantians is complex, but the bottom line is this: neo-Kantianism was a failure on its own terms, but bequeathed problematics that are still with and part of the human sciences; Dilthey recognized the tensions between the elements of his own thought,

which included Kantian elements, and never fully resolved them, but did develop his ideas in a direction that points directly to later human science.

For the Kantians, the characteristic problem is objectivity. The central question is how, given this dependence of knowledge on our construction of the world, is objectivity possible. For Kant, the answer was that there was only one correct and necessary construction of the world. Neo-Kantianism abandoned this, but only in part. Neo-Kantianism is often dated to the 1872 dissertation of Hermann Cohen, which purported to explicate Kant, but in fact turned him on his head. Cohen's reasoning was this:

> If … I take cognition not as a form and manner of consciousness, but as a *Faktum* that has established itself in science and that continues to establish itself on given foundations, then the enquiry is no longer directed to a subjective fact; it is directed instead to a fact that, to whatever extent self-propagating, is nevertheless objectively given, a fact grounded in principles. In other words, the enquiry is directed not to the process and apparatus of cognition, but to its result, to science itself. Then the unequivocal question arises: from which presuppositions does this fact of science derive its certainty? (Paulson, 1992: 330)

Rather than grounding science against the skeptic, as Kant meant to do, Cohen took the existence of an ordered body of knowledge as itself the objectively given fact, a fact that needs to be understood by identifying the presuppositions that make this fact possible.

This reasoning was soon generalized from physics to other domains of knowledge – historical knowledge, law, theology, and eventually to sociology, first by Georg Simmel and then by many other conceptual system builders. Each of these domains could be understood as conceptually self-constituted, distinct, and made distinct by the different grounding or organizing concepts that the everyday factual assertions within these domains presupposed.

By the end of the nineteenth century, when this strategy was at the peak of its influence, the entire neo-Kantian project of understanding domains as conceptually preconstituted, organizable into a scheme of intelligible categories (which could be discovered by conceptual analysis), was beginning to break up. The problem was relativism: the prospect of multiple presuppositional 'constitutings' of the subject matter in a domain, or defining a domain, fatally undermined the circular notion of a *Faktum der Wissenschaft*, which depended on the idea that one was not merely imposing a frame or 'lens' but identifying the facts in terms of the uniquely necessary conceptual structure of the science itself, and validating this structure by reference to a uniquely valid description of the facts themselves.

Dilthey and the Human Sciences

Dilthey was the thinker who put these issues together, in the form of a full consideration of the prospects of the human sciences as an alternative to the conception found in Mill and Comte. Although his basic starting point was Kantian, and concerned with systematic knowledge, he added to this the distinctive problem of human experience. We can think of the problematic of the human sciences in terms of a Kantian triangle: experience, the concepts forming the experiences, and the objects, texts, overt practices, and externals that are given meaning by humans. The neo-Kantians de-emphasized experience in favor of the concepts forming it and the evidence of concepts and their order. This led to a model of particular orders of life that was itself rigid, while life itself was not: human experience flowed and changed. Dilthey insisted on reminding the neo-Kantians that their constructions of experience were abstractions. But at the same time he argued that we have access to experience.

> The human sciences have the advantage over the cognition of nature that their object is not mere appearance given in external sensation as the mere phenomenal reflex of something real but an immediate reality itself. And this reality, moreover, is given in the form of a coherence experienced from within. Yet the very manner in which reality is given in inner experience gives rise to great difficulties in apprehending it objectively. (Dilthey, 1957: (*Gesammelte Schriften* vol. 5), 317–318); cited in Ermarth, 1978, 99)

Experience is thus a problem and an opportunity: an opportunity because we have a means other than reason and inference to understand others and the experiences we share with them, namely *Verstehen* or understanding as distinct from *Verstand*: "We explain through purely intellectual processes, but we understand through the cooperation of all the powers of the mind activated by apprehension" (Dilthey, 1957: (*Gesammelte Schriften* vol. 5), 172). And our capacity to understand, which depends on all our capacities as experiencing beings, allows us access to the experiences of others, such as the figures of history.

He also stressed another difference between the human and the natural sciences: relexivity. As he put it, "in the human sciences there prevails a special fundamental relation (*Grundverhaltnis*) such that we are living in society at once as an active agent (*wirkendes Element*) and also as aware of our effects (*unserer Wirkungen uns bewusst*)" (Dilthey, 1977: (*Gesammelte Schriften* vol. 18), 18; cited in Ermarth, 1978: 107). But also that we are both the products of our society and culture and their maker: "conditioned and unconditioned" (*bestimmt-unbestimmt*) ("Die Breslauer Ausarbeitung" (unpublished), 99; cited in Ermarth, 1978, 121).

The possibility and necessity of reflection on this situation is distinctive to the human sciences. And it leads to the conclusion that "we belong integrally to a total mental realm of which we are a part" (Dilthey, 1957: (*Gesammelte Schriften* vol. 5), 35; cited in Ermarth, 1978, 121). "The foremost trait of the individual is that it lives in something which is not itself" (Dilthey, 1959: (*Gesammelte Schriften* vol.1), 30; cited in Ermarth, 1978: 121). This led Dilthey to an insistence on the importance of culture as the total mental realm of which we are a part, but also to an insistence on the non-fixity of the mental realm, the vitality of the course of life, and the impossibility of the kind of neat reductions of a realm of thought to a hierarchy of conceptual relations central to neo-Kantianism. With Dilthey, as we have seen, there are differences in emphasis between different approaches to the human sciences with respect to which of these are prioritized. Nevertheless, the

central problem of the human sciences is that concepts and the subjective experiences of others need to be inferred from externals of some kind, including traditional sources, such as historical documents, but also more generally the externals of human action and expression.

Later History

The subsequent history of the human sciences does not follow a direct path. Two major influences, Durkheim and Weber, bear on the development of these ideas, but neither falls neatly within this development. Works in philosophy, such as Gaston Bachelard's *Poetics of Space* (1994), the *Annales* School of historians and its focus on mentalities, the rise of humanistic or phenomenological psychology and sociology, and the focus on everyday life of Walter Benjamin and French Marxism, all contribute more directly.

Durkheim's 'scientific' ideas, notably his ontology of the collective consciousness, were being abandoned or de-emphasized by the time of his death, but other 'Collective' ideas, especially those associated with cultural differences, collective memory, and techniques of the body, were promoted by the followers of Durkheim. One of the surviving ideas was the notion that the fundamental categories of thought were 'social.' With the emphasis on mentalities of the *Annales* School of historians, this produced a kind of working consensus about the pervasiveness of cultural influence and the possibility of studying it, especially through artifacts. An influential example of this kind of thinking was the work of Philippe Ariès on the history of childhood (1962). By looking at paintings and other expressions of culture, including books of advice, he showed that the concept of childhood had changed, and that childhood in the modern sense was an invented category.

Weber's influence was on the opposite pole: his argument that direct observational understanding of meaning was possible, and that explanations of action required both adequacy at the level of meaning and adequacy at the level of cause, together with the example of his own influential imaginative reconstruction of the mental and motivational work of Protestant early capitalists, had an important role. It validated the 'scientific' status of *Verstehen*, and also provided a model of social science hermeneutics.

The idea of culture, however, in a sense similar to Durkheim's, became a staple of French thought, a central element of the human sciences, and evolved in a way that merged with the concept of ideology, and provided the human sciences with a means of critique. This was a merger foreordained in the experience of neo-Kantianism. The experience of neo-Kantianism was that the frames which could be constructed to account for and provide conceptual order to a domain by identifying its presuppositions produced a serious problem of underdetermination. A domain like the law could be made sense of in terms of a variety of conflicting concepts – justice, equity, equality, fairness, legal validity, legal certainty, and so forth. Some of these accounts reflected political or valuative positions. Each of them could be interpreted as favoring one side or another in the social and political conflicts of the period.

Methodological Problems

The human sciences faced this diversity of analytic perspectives as a second-order problem. At the first level, the problem of the human sciences was to identify the frames, presuppositions, and categories that the participants themselves used to order their existence. The second-order problem was to select the account of these frames that provided a vocabulary for talking about them. When Foucault (1990: 257) discusses problematization, he characterizes it in these terms: "the totality of discursive or non-discursive practices that introduces something into the play of true and false and constitutes it as an object for thought (whether in the form of moral reflection, scientific knowledge, political analysis, etc.)." This captures some key ideas: the notion that there is a totality made up of mental or discursive elements that organize and present the world to us as meaningful and truth-relevant.

At the second level, however, there were many variations of these ideas. They range from the 'Structuralism' of thinkers like Claude Levi-Strauss to the more phenomenological reconstruction of lived experience through narrative. The difference is this: for the structuralist, the ordering principles need not be at all close to the conscious awareness of those whose conduct is being explained. They are mental, and shared, but they are revealed from the organization of such things as artifacts, the physical layout of villages, or the inner logic of myths exhibiting binary oppositions. In contrast, for the analyst concerned with lived experience, it is important to closely match and analyze the conscious life and thought of the subject, in spite of the fact that the researcher must rely on external evidence. This is of course another form of Dilthey's problem of the impossibility of capturing 'life' in thought and the necessity of relying on external facts to make inferences about the organizing mental frame on which our individual thought depends.

Karl Mannheim creatively extended the basic model of neo-Kantian constitution of objects of thought to the world of political ideology, and what he called 'utopias.' His thought was that utopias were partly true but idealized characterizations of real states of affairs that gave the appearance of reality. He quotes Droysen's idea of history as the realization of ideas:

> All movement in the historical world goes on in this way: Thought, which is the ideal counterpart of things as they really exist, develops itself as things- ought to be … (Mannheim, 1936: 199, §77)

as well as Droysen's comment on the implications of this for critique:

> Thoughts constitute the criticism of that which is and yet is not as it should be. Inasmuch as they may bring conditions to their level, then broaden out and harden themselves into accord with custom, conservatism, and obstinacy, new criticism is demanded, and thus on and on. (1936: 199, §78)

Reality is not yet in accord with the idea: thus it is open to critique from the standpoint of the idea. But the normal situation, Mannheim argues, is one in which the utopian thinker

transforms immediate experience in accordance with the organizing principle of the utopian image and wish:

> the utopian element—i.e. the nature of the dominant wish—which determines the sequence, order, and evaluation of single experiences. This wish is the organizing principle which even moulds the way in which we experience time. (1936: 209)

In short, experience itself is distorted or molded in a way that conceals reality and makes it appear in experience in accordance with the utopian wish. A similar idea of misrecognition is central to Foucault and Pierre Bourdieu. The thought is that it is intrinsic to the manner of thinking or ideology that it misrepresents or conceals aspects of reality, and that these aspect can be revealed, non-ideologically, by the analyst-critic.

The special value of these approaches has been in the way they have expanded the range of subject matter. The more 'experience' oriented approaches have revealed a great deal about the subjective experiences of social actors, and explored the diversity of subjective experiences, particularly with respect to gender and the experience of social exclusion. The kinds of analysis more oriented to external objects has brought into view a wide range of cultural objects and provided a second order account of their meaning, especially their role in misrecognition. These analyses have provided new accounts of exclusion and domination through practices that are nominally neutral or directed toward other purposes.

Nevertheless, there are issues with these techniques of analysis. The problem of circularity is central: the 'externals' used for the analyses are given meaning and selectively appropriated to provide a subject matter for analysis; the constitutive frame ascribed to the participants is inferred from the meanings of the external facts that are analyzed. This is a direct inheritance from neo-Kantianism, with the same result: a vast diversity of analyses. The inference to the frame is itself problematic. Not only is there a high degree of underdetermination in reasoning from an assemblage of meaningful things to the supposed presuppositions or constitutors of meaning, the argument is essentially functionalist.

The functionalist character of the reasoning (the end being the meaning of the objects or external facts, the frame functioning to give it a specific meaning) is especially problematic in connection with claims about misrecognition. Misrecognition implies that there is a purpose to the frame, namely to exclude or oppress, and the analyst infers this purpose or function from the facts of exclusion. But there is no feedback mechanism that assures that this purpose will continue to be pursued. So there is no way to assure that the oppression and exclusion are not merely accidental by-products of a given arrangement, and not its purpose.

These very abstract considerations can be brought to earth by considering their bearing on claims about racism and sexism: Are ostensibly neutral practices racist or sexist? The mere fact that their application leads to exclusion or oppression does not make them so. There needs to be a kind of purposive force. And inferences to this kind of force require evidence of feedback, or of some sort of supra-individual agent, which is not available. So these arguments collapse into functionalism (Elster, 2010).

The Sociology of the Human Sciences

The relation of the human sciences to ideological and political concerns has often been close. The fact that some core human science concepts lead directly to the possibility of critique has made them attractive to particular social and political movements. Foucault and Bourdieu, for example, provided analyses that were particularly influential on the Left and for feminism. The notion of misrecognition could be used as means of unmasking liberal ideological constructions of bureaucratic practices. Bourdieu and Jean-Claude Passeron's *Les Heriters* (1964), for instance, became an influential book among the teachers who worked in the educational system it described, which interpreted the 'neutral' liberal standards of the educational system as means of reproducing class distinction. A large part of the popularity of these thinkers was a result of these political affinities. But the history of the human sciences contains some quite different affinities. Werner Sombart's nationalistic methodological work, *Die Drei Nationaloekonomie* (1930) associated the need to understand experience through *Verstehen* with the German character, and derived this methodological impulse from Goethe and Nietzsche, and opposed the alien use of abstractions in economics. The concept of *Volksgeist*, notoriously, served nationalistic purposes.

Yet the most important 'sociological' aspect of the notion of the human sciences has been its role in opposing scientistic forms of social inquiry, and indeed the image of the social sciences as scientific in the sense of the natural sciences. By implicitly pointing to the specifically human aspect of these sciences – the fact of intelligible human experience – the term grounds a rejection of the reduction of this experience to quantification or experiment.

Abstract

The ability to spatially orient is one of the most complex cognitive skills. It relies on the processing of different spatial information available in the environment, leading to the use of different cognitive strategies useful for orientation. The neural mechanisms underlying such a complex phenomenon include networks that require the proper functioning of a variety of cortical and subcortical regions. Here, we review the basic behavioral and neural mechanism responsible for the ability to orient in spatial surroundings, as well as its development (and lack of) in children.

Humans Navigate Using Egocentric and Allocentric Spatial Information

The ability to navigate in spatial environments is one of the most fundamental behaviors that animals and humans display. It allowed our ancestors to hunt and forage, explore new environmental niches, and settle communities. It remains a critical ability in the modern world by allowing humans to wayfind through increasingly complex and distributed urban surroundings.

Humans navigate through environments by relying on two forms of topological memory that produce spatial representations differing in frames of reference, learning strategies, and neuroanatomical structures. The first memory system generates egocentric spatial representations that are used to guide wayfinding to locations in a person's immediate environment by relating spatial information to the body of the individual (Mou et al., 2008). The second memory system generates allocentric spatial representations that are used to guide wayfinding to locations outside of a person's immediate environment by using long-term memories about the arrangement of environmental landmarks independent of a person's actual location.

Egocentric Spatial Representations Are Generated in the Parietal Cortex

Past research in animals and humans suggests that Brodmann area 7a in the posterior parietal cortex (PPC) is the primary cortical area involved in generating and maintaining the egocentric spatial representations used for navigation (Burgess et al., 2001; Byrne et al., 2007). While sensory, information from the environment is processed in modality specific areas of the brain, area 7a and other posterior and medial regions in the parietal cortex integrate inputs from these sensory areas into sensorimotor maps. These sensorimotor maps code body-to-object relationships that can be used to guide wayfinding by outputting signals to the motor cortex. Neurons in area 7a exhibit 'gain field' responses that modulate their firing rate to visual stimuli depending on (1) the orientation of gaze direction relative to the head (Andersen et al., 1987), (2) the orientation of the head relative to the body, and (3) the orientation of the body relative to the environment (Snyder et al., 1998). These gain field responses are believed to allow for effective and coordinated translations between the various body-centered egocentric reference frames necessary for movement through spatial environments (Burgess, 2008; Deneve et al., 2001; Zipser and Andersen, 1988).

Sequence-based circuit dynamics in the PPC have been shown to provide stable firing characteristics in relation to egocentric navigation, suggesting that parietal-based spatial representations rely on a form of working memory that encode environmental information relevant to a current navigation task. Using two-photon microscopy to image layer two-thirds of PPC neurons while mice ran through a virtual T-maze, Harvey et al. (2012) found that temporal sequences of parietal neurons in mice predicted whether a left or right turn was made at the T intersection, a decision based on visual cues located early in the maze that coded the location of a reward. The researchers found that left and right, turns produced dissociable temporal sequences between the visual cue and the decision point at which a turn was required. High variability in the temporal sequence was found to be associated with a response error on that trial. This suggests the firing dynamics of certain PPC circuits specify choice-related information and may provide the basis for a spatial working memory system that is essential for movement planning and navigation. Additionally, the researchers found that the active cell in the sequence encoded information about the spatial and temporal progression through the maze independent of actual location. These findings imply that the PPC is able to use circuit dynamics to encode choice-specific information related to accurate navigation, as well as progression through an environment by self-motion, independent of location in the maze.

Allocentric Spatial Representations Are Processed in the Medial Temporal Lobe

The ability to represent the spatial layout of environmental features is contingent upon the effective integration of various types of neurons in the medial temporal lobes that exhibit distinct firing properties in relation to certain aspects of space.

These cell types are known as place, head direction, grid, and view cells.

Place Cells

Through an elegant set of studies in the 1970s, O'Keefe et al. provided the first evidence that a subset of neurons within the rat hippocampus fired when the animal entered a specific area of an environment (O'Keefe and Dostrovsky, 1971; O'Keefe, 1976; O'Keefe and Nadel, 1978). Termed 'place cells,' these neurons display place fields – receptive fields within an environment – where there is an increase in firing rate as the rat approaches a specific location in the environment. Although one place cell represents a limited portion of an environment, taken as a population the hippocampal place cells are able to represent any location through a unique combination of firing rates from different place fields. Based on these findings, O'Keefe and Nadel (1978) hypothesized that place cells serve as the neural basis of a cognitive map, an internal representation of the spatial layout of an environment and spatial relationship between landmarks within it, that is used by animals and humans for flexible and efficient navigation.

Subsequent studies on the signaling properties of place cells suggest possible mechanisms through which place fields are generated. Looking at the influence of environmental landmarks, Muller and Kubie (1987) found that a white cue card placed on the boarder of a gray cylinder produced a set of distinct place fields. When the experimenters rotated the white cue card along the edge of the cylinder, they found that the associated place fields rotated to a similar degree. However, the place fields randomly changed their angular location when the cue card was removed, although they remained, firing in only a single location. This suggests that salient landmarks are able to modulate place fields but are not necessary for their ongoing activity. These findings provide converging evidence toward one of O'Keefe's (1976) original findings that place cells persist even in dark environments when landmarks are not viewable.

If place fields are not fixed to environmental landmarks, how else might they be generated? A study by Sharp et al. (1995) suggests that vestibular signaling plays an equally important role in stabilizing place fields. The researchers recorded place fields in a black and white striped cylinder that was constructed so that the walls and the floor could be rotated independently. They found that when the walls and floor were slowly rotated together in the dark, the place fields rotated as well. However, when either the floor or the wall was rotated quickly with the lights on, the place fields remained stable. It was concluded that the rats could use vestibular cues about self-motion to detect incongruences between self-motion and visual inputs. Another prominent model that has been proposed to modulate place fields is the 'boundary vector model' (Hartley et al., 2000). Under this model, boundary vector cells (BVCs) – neurons with receptive fields that increase firing when moving toward an environmental boundary – are input to hippocampal place cells, which sum the BVC inputs and generate place fields at a given location relative to the surrounding boundaries.

Place cells have also been directly recorded in the human hippocampus and parahippocampal region. By implanting electrodes in the medial temporal lobes of patients with epilepsy, Ekstrom et al. (2003) recorded from 317 neurons while patients played a navigation game in a simple virtual environment. The researchers observed that 26% of the cells responded to the patient's location in the environment, 21% responded to the desired destination of the game, and 12% responded to views of specific landmarks. Of the cells in the hippocampus, 24% were bona fide place responsive cells. Studies in humans using functional magnetic resonance imaging (fMRI) have supported the role of the hippocampus in encoding and using cognitive maps of virtual environments (Hartley et al., 2003; Iaria et al., 2007; Iaria et al., 2003; Maguire et al., 1998).

Head Direction Cells

Just as place cells are able to represent an individual's location independent of the orientation of their body, scientists have discovered a cell class that represents the orientation of an individual's head independent of their actual location. Termed 'head direction' (HD) cells, these neurons fire over a rotational range of 90° with maximal firing occurring near the middle of the range (Taube et al., 1990a) and are contingent upon the orientation of the head within an environment. Different HD cells fire at different orientations so that the entire 360° range can be represented by the combination of relative HD cell firing rates (Taube et al., 1990b). These cells are largely found along an anatomical circuit that resembles Papez's circuit (Papez, 1937), stretching from the dorsal tegmental nucleus to the lateral mammillary nucleus and the anterior thalamus into the postsubiculum. HD cells have also been found in the retrosplenial (Chen et al., 1994) and medial entorhinal cortex (Sargolini et al., 2006).

The HD cell signal is believed to arise from angular head velocity signals produced by the vestibular system. Lesion studies in rats provide support for this by showing that disruption of the vestibular system removes the directional firing of HD cells along the anterior thalamic nucleus (Stackman and Taube, 1997). Salient environmental landmarks, as well as the geometry of environmental boundaries, have also been found to modulate the directional orientation of HD cell firing fields (Taube et al., 1990b), suggesting that HD signals may be modulated in part by visual input.

Grid Cells

First described in 2004 by Fyhn et al. (2004), 'grid' cells represent one of the most important discoveries in understanding the cellular basis of how the brain maps spatial environments. These cells are located primarily in the medial entorhinal cortex and display multiple place fields arranged in a triangular grid. Like place cells, the relative firing rate of grid cells at a population level is able to represent the entire spatial layout of an environment. As such, grid cells have been proposed as an alternative means through which location in an environment can be represented and their firing properties have been shown to influence place cell activity (McNaughton et al., 2006; Fyhn et al., 2007) through projections from the dorsal medial entorhinal cortex to the dorsal hippocampus.

Systems neuroscience models of grid cell dynamics hypothesize that speed-modulated signals from HD cells input to velocity controlled oscillators that form the basis of grid cell activity (Burgess et al., 2007; Jeewajee et al., 2008). Supporting these models, the deep layers of the medial entorhinal cortex have been found to contain not only grid cells, but also HD cells and conjunctive cells that represent an individual's location and head orientation (McNaughton et al., 2006; Sargolini et al., 2006). This integration of speed, velocity, and orientation information in the medial entorhinal cortex has led some researchers to suggest that grid cells form the basis of a path integrator that allows for navigation through environments using path integration (i.e., updating of location relative to a fixed point by using self-motion cues about spatial displacement) (Fyhn et al., 2007; Hafting et al., 2005; McNaughton et al., 2006). McNaughton et al.'s (2006) model builds on the idea of a path integrator and suggests that the outputs of grid cell firing into the hippocampus are used to set the spatial scale upon which the size of place fields are generated.

View Cells

Spatial view cells are neurons in the human parahippocampal region that have been found to display selective firing when an individual looks at a certain object or person within a spatial environment. In their study using electrodes implanted in epileptic patients, Ekstrom et al. (2003) found that 88% of view cells fired preferentially to a single object during navigation through a virtual town. These cells were found to be either location dependent (30%) or location independent (70%), the latter responding when an object was viewed from any position within the environment. The prevalence of location-independent view cells led the researchers to hypothesize that the parahippocampal region is extracting allocentric information based on salient landmarks, and inputs a coarse representation of space to the hippocampus. The hippocampus then integrates various inputs into a flexible cognitive map of the environment used for navigation. The role of the parahippocampal region in processing allocentric representations of space is supported by the research by Epstein and Kanwisher (1998) on a 'parahippocampal place area' identified using fMRI in humans, which is believed to encode the geometry of local spatial environments.

Hippocampal Structure and Function Are Associated with Allocentric Spatial Representations in Humans

Converging with Ekstrom et al.'s (2003) findings on place and view cells in the human hippocampus, numerous brain imaging studies have further implicated the hippocampus as a critical structure underlying the formation and use of allocentric spatial representations during navigation. Wolbers and Büchel (2005) found that the hippocampus was necessary for learning the spatial layout of a virtual environment, and that activity increased in the left hippocampus on trials where the greatest spatial learning was required. Similarly, Iaria et al. (2007) found that the left anterior hippocampus was preferentially engaged while participants learned the spatial layout of six landmarks in a virtual city. However, the researchers found that the right posterior hippocampus displayed increased activity while participants used their knowledge of the arrangement of landmarks to navigate between them in the shortest route possible. This suggests a possible dichotomy between the functional role of the left and right hippocampus in relation to encoding and using a cognitive map within a virtual environment.

The functional role of the hippocampus was comprehensively evaluated in a study by Spiers and Maguire (2006). The researchers scanned the brains of London taxi drivers while they navigated through an interactive virtual simulation of London. The task required that the participants engage in both directed (i.e., computer generated) and spontaneous route planning. After the scan session, the researchers asked that the taxi drivers watch a video that had been recorded of them performing the task and give a verbal description of what they were thinking during the experiment. This allowed them to pair neural activity with in-task demands, as well as subjective cognitive processes. The researchers observed that the left hippocampus, but not the right, showed increased activity while planning directed routes. However, neither the left or right hippocampus showed increased activity during spontaneous route planning. These results suggest that the role of the hippocampus during human navigation may be somewhat transient, showing increases in neural firing during periods of attentive route planning.

Variability in the structural characteristics of the hippocampus has also been found to be significantly related to navigation skills in humans. A study by Bohbot et al. (2007) found that participants who used a spatial learning strategy during a radial arm maze task had significantly more gray matter in their hippocampus than nonspatial learners. Conversely, the nonspatial learners were found to have significantly more gray matter in their caudate nucleus, an area associated with response learning during wayfinding. The influence of hippocampal microstructure was further evaluated by Iaria et al. (2008) in a diffusion tensor imaging study. Participants with high fractional anisotropy – a, measure of the structural integrity of brain structures – in their right hippocampus were found to encode allocentric spatial representations quicker and were able to use them more efficiently to orient and navigate within a virtual environment.

Egocentric and Allocentric Spatial Representations Are Integrated across a Distributed Brain Network into Mental Representations of an Environment

A direct implication from the decades of research on single and multicell recording in animal models is that spatial navigation occurs through a distributed brain network that integrates various features of space into a flexible mental representation. Positron emission tomography (PET), fMRI, and electroencephalography studies in humans have begun to illuminate the intricacies involved in the neural systems underlying spatial navigation and given insight into the neural basis of cognitive maps.

One of the pioneering studies on the human navigation network was carried out by Maguire et al. (1998) using PET imaging while participants navigated a virtual town. The researchers found widespread activity throughout the brain in structures that were homologous to spatial areas identified in animal models. Of particular interest was regional activity in the right hippocampus, which reflected accurate navigation through the town, and in the right caudate nucleus, which correlated with speed of navigation. These two areas were supported by activities in inferior and medial parietal regions, suggesting that allocentric spatial representations processed within the medial temporal lobes were being integrated with egocentric representations in the parietal cortex in order to successfully navigate through the town.

The differential engagement of hippocampal and caudate structures during navigation were further delineated through a series of studies in the 2000s. Iaria et al. (2003) asked individuals to solve a virtual-arm radial maze while they recorded brain activity. The authors found that participants were able to solve the task by spontaneously using one of two different strategies: a spatial strategy in which individuals made use of environmental landmarks in order to get to different locations, or a nonspatial strategy in which they navigated by counting number of turns without relying on environmental landmarks. The researchers found that the spontaneous use of spatial vs nonspatial strategies in humans correlated with increased activity in the hippocampus and caudate nucleus, respectively. Similar findings were reported by Hartley et al. (2003) who showed that good navigators used a hippocampal dependent system, while wayfinding and a caudate dependent system while following an explicit route. This hippocampus/caudate nucleus dichotomy was taken further in a study by Marchette et al. (2011). The researchers showed that variability in place vs response strategies during navigation could be explained by the proportional engagement of the hippocampus and caudate nucleus relative to one another. Taken together, these studies suggest that there is interindividual and task specific modulation of a core network that supports spatial navigation, and that variability in this modulation can influence spatial behavior.

Systems neuroscience models put forth by Burgess et al. (Burgess, 2008; Burgess et al., 2001; Byrne et al., 2007) describe a computational perspective on how medial temporal-based allocentric representations and parietal-based egocentric representations integrate within the human brain. These models suggest that hublike structures in the cortex – the precuneus, retrosplenial cortex, and hippocampus, primarily – integrate allocentric spatial representations that code landmark and location-dependent information with egocentric spatial representations that code spatial information in the immediate environment. The result is a flexible mental representation – a cognitive map – that can be used to simulate movement through space and plan routes to guide wayfinding. Arnold et al. (2013) complement this model from a cognitive perspective by hypothesizing that the navigation strategies used by humans exist on a continuum defined by the degree of integration, where highly efficient modes of navigation require coordinated processing of both egocentric and allocentric spatial representations.

Variability in Large-Scale Neural Network Dynamics Influences the Capacity to Navigate Using Mental Representations

While systems neuroscience models provide a comprehensive account of the computational processes that underlie spatial navigation, they provide limited insight into how variability in network dynamics influences spatial behavior. To address this, Arnold et al. (2013) investigated whether individual variability in using egocentric and allocentric spatial representations to accurately orient could be explained through variability in certain network dynamics. The researchers had participants perform an fMRI study where they (1) encoded the spatial layout of a virtual city and (2) used landmarks within, the city to make orientation decisions. Analysis of the whole group data revealed engagement of a canonical navigation network during the encoding task and engagement of a retrosplenial-based system during the orientation task. However, when accuracy of orientation performance was included in the analysis, good performers were found to engage an additional network involving the left hippocampal region and the right supramarginal gyrus over and above the network expressed by the whole group. This suggests that variability in the configuration of task-related functional networks influences the ability to integrate allocentric and egocentric spatial representations for the purpose of orientation.

The researchers then used the functional networks identified during the orientation task in a resting-state fMRI analysis to further investigate whether variability in network properties influenced spatial behavior. Two specific topological characteristics indexing network integration were evaluated using graph theory – global efficiency across the entire functional network and node centrality of the additional network regions expressed by accurate participants. Both whole network global efficiency and node centrality in the left hippocampal region were found to be highly predictive of accuracy, during the orientation task. These results suggest that intrinsic connectivity properties of functional networks measured during rest influence the degree to which individuals are able to generate mental representations in order to effectively orient. Similar results have also been documented in the neural encoding of spatially relevant landmarks, where connectivity measured through resting-state fMRI signal between the hippocampus and parahippocampal gyrus relates to an individual's navigation ability (Wegman and Janzen, 2011).

Children's Ability to Navigate Is Related to the Development of Specific Functional Brain Networks

Development of spatial cognition in children is supported by prominent functional and structural brain changes that occur in a nonlinear fashion (Johnson, 2001). A longitudinal study of children and adolescents between the ages of 4 and 21 years showed that gray matter first matures at the primary sensorimotor cortex, and the frontal and occipital pole. The remaining higher order cortical areas develop in a parietal to frontal direction, and the superior temporal cortex is last to mature (Gogtay et al., 2004). There are also significant

large-scale structural network changes in terms of topological properties – brains of children older than 8 years of age begin to exchange local efficiency and modularity for increased global efficiency. In addition, the number and distribution of connector hubs show age-related variations that eventually localize to multimodal association areas. Finally, interregional structural connectivity increases in areas that are the last to mature (Khundrakpam et al., 2012).

These developmental patterns underlie the acquisition of spatial orientation skills, which progresses from using simple environmental cues to forming complex mental representations of large-scale environments. Children as young as 8-month old show primitive beacon use by associating a cue object with a goal location during visual searches (Crowther et al., 2000). With mobility, infants begin to use beacons as distant clues to orient toward. Higher level encoding of body movement after the first year of life forms the basis of path integration and allow children to continuously update their spatial location from vestibular and proprioceptive systems (Loomis et al., 2001). Parietal and frontal lobe maturity is accompanied by increased attention, executive function, and memory skills, and as a result, children are better able to encode distances and direction between landmarks and goal locations (Bushnell et al., 1995). Language (Shusterman et al., 2011) and body orientation (Wang and Spelke, 2002) further support children in heading orientation and learning routes based on sequential turns. Finally, a protracted development of the temporal lobe result in complex cognitive maps as one of the last spatial orientation strategies to mature (Piper et al., 2010).

There has been limited study into developmental disorders of orientation skills in children. To date there are published examples of congenital malformations (Griffiths and Hunt, 1984; Iaria et al., 2005), perinatal injury (Brunsdon et al., 2007; Pavlova et al., 2007), and early traumatic brain injury (Lehnung et al., 2003) resulting in topographical disorientation, but full descriptions of the deficits are restricted to isolated case studies. Specific visuospatial deficits associated with impaired orientation skills have been demonstrated in William's syndrome (Nardini et al., 2008) indicating a possible model to investigate how genetic differences may contribute to navigation capacity. The careful study of individual variability or deficits in orientation skills as they emerge during childhood may provide better understanding of brain development and the neurobiological underpinnings of these skills (Anderson et al., 2011). The interaction of different lesions through periods of development has potential for illuminating the brain's strategies for adaption to insult.

Recently, a set of case studies describing a newly identified condition termed developmental topographical disorientation (DTD) (Iaria and Barton, 2010; Iaria et al., 2009) provide evidence that the lack of development in the ability of children to mentally represent an environment can occur in the absence of brain lesions. In the first documented case study, Iaria et al. (2009) describe an individual who was unable to generate cognitive maps of novel environments despite having no other cognitive deficits or structural abnormalities in the brain. Using fMRI, the researchers measured brain activity while this individual explored a virtual environment with several distinct landmarks. Compared to a control group, this individual displayed significantly lower brain response in the hippocampus and retrosplenial cortex while attempting to encode the spatial layout of the virtual city. Though based on a single case, these results suggest that within DTD there is selective disengagement of brain regions critical for encoding the arrangements of landmarks, which may translate into a selective impairment in generating cognitive maps. A follow-up study on 120 new cases of DTD (Iaria and Barton, 2010) supports the findings described in the original first case, where the ability to encode cognitive maps, was the primary navigation skill impaired on a test battery assessing a variety of orientation skills. The neural mechanisms underlying this unique developmental condition are under investigation. However, given the knowledge gained in the last few years, it is reasonable to speculate that a selective orientation defect as described in individuals with DTD may be related to the lack of proper functional connectivity between the various brain regions critically involved in the complex phenomenon of spatial orientation.

Human Terrain System (United States): Critique

Maximilian C Forte, Concordia University, Montreal, QC, Canada

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The U.S. Army's launch of the Human Terrain System (HTS) in 2007, initially attempting to incorporate anthropologists into a program designed to gather 'ethnographic intelligence' in support of counterinsurgency requirements, arguably met with limited success and spawned intense debate through 2011. While the HTS involved a range of social scientists and regional experts, anthropologists in US universities almost exclusively dominated in articulating critiques of HTS. Fundamental ethical, methodological, and certain theoretical tools of the discipline were put to the test, and sharpened. Yet some critical political positions were marginalized, while key epistemological and political stances on other arenas of collaboration with the state, and the nature and scope of critique itself, were at best addressed ambiguously.

Unfolding with particular intensity from late 2007 through 2011, debates abounded about the role of academics, and specifically anthropologists, in the U.S. Army's Human Terrain System (HTS) program. Especially challenging for an understanding of what was argued and why is the fact that there were several very different critiques that often contrasted with one another. On one side, criticisms of HTS were to be found among those employed in the program, whether military or civilian; among disillusioned former proponents of the program, in academia; and within the military that housed HTS. HTS suffered from numerous defectors, dissenters, and internal whistleblowers.

The production of multiple variants of human terrain analysis at various levels of the U.S. military and intelligence was also sometimes accompanied by either implicit or explicit attempts to distance these variants from HTS, creating a sense that HTS was viewed by even those closest to it – in institutional and political terms – as a potential embarrassment. One might also argue that HTS itself emerged as a debate, at least in part, in the form of a critique of now mainstream anthropology. On the other side, diverse criticisms emerged from the American Anthropological Association (AAA), from the independent Network of Concerned Anthropologists (NCA), and from disparate activists, independent journalists, and bloggers in anthropology, both within the United States and abroad. These different, though related, actors tended to bring to the fore qualitatively divergent critiques, using different reasoning, and to different ends. Yet, on some key issues, most of the dominant voices in the debate sometimes tended to agree. The resulting picture is complex enough that it is only with considerable difficulty that one could argue that any one side of this intellectual and political struggle had somehow succeeded in achieving all of its key aims by the end of this period.

Theory and Practice of the HTS

With the war in Iraq beginning to turn against US-led forces by the end of 2003, marked by increased casualties inflicted by Iraqi resistance fighters and the emergence of increasingly sophisticated and lethal 'improvised explosive devices' (IEDs), some in the U.S. military felt that while technologically superior, their forces could not win the war to pacify Iraq without some drastic change in thinking and practice on the ground. The abundance of 'situational awareness' (e.g., where Iraqi tank units were located) was cast as inadequate when what was really needed was 'cultural awareness' to understand the implacable resistance in order to defeat it. This new approach was varyingly called 'culture-centric' or 'population-centric,' and as Scales (2004) explained, "wars are won as much by creating alliances, leveraging nonmilitary advantages, reading intentions, building trust, converting opinions, and managing perceptions – all tasks that demand an exceptional ability to understand people, their culture, and their motivation.

These imperatives place an increased premium on the ability of the U.S. military to understand the nature and character of war, as well as the cultural proclivities of the enemy" (see also McFarland, 2005). Declaring current US occupations to be part of 'World War IV,' Scales also asserted that 'culture awareness' and the ability to "build ties of trust [that] will offer protection to our troops more effectively than body armor." He concluded: "To win World War IV, the military must be culturally knowledgeable enough to thrive in an alien environment. Victory will be defined more in terms of capturing the psycho-cultural rather than the geographical high ground. Understanding and empathy will be important weapons of war" (Scales, 2006). General David Petraeus, once widely proclaimed to be the intellectual grandmaster of contemporary counterinsurgency theory, standing out for his academic qualifications, similarly argued that the decisive terrain of warfare would the 'cultural terrain': "cultural awareness is a force multiplier, reflects [*sic*] our recognition that knowledge of the cultural 'terrain' can be as important as, and sometimes even more important than, knowledge of the geographic terrain.

This observation acknowledges that the people are, in many respects, the decisive terrain, and that we must study that terrain in the same way that we have always studied the geographic terrain" (Petraeus, 2006: p. 51). In advocating what some misinterpreted as a 'gentler' approach to war, "emphasizing cultural knowledge and ethnographic intelligence as major components of its counterinsurgency doctrine," what was formulated was an allegedly new 'cultural turn,' one that

required the expertise of anthropologists in particular in order to understand 'adversary societies' (Jager, 2007: p. v). An early attempt to define the 'human terrain' concept as "the human population and society in the operational environment as defined and characterized by socio-cultural, anthropologic, and ethnographic data and other non-geophysical information about the human population and society" was, however, both overly broad and internally repetitive (Kipp et al., 2006: p. 14, fn 2). These, nonetheless, were some of the main founding lines of thinking on which HTS was instituted.

Putting this thinking into practice, some of the first advocates and directors of HTS came together specifically to counter the impact of IEDs in Iraq, in what was a founding platform for HTS as a practice, identifying the bomb makers as the intelligence priority rather than focusing on the bomb technology alone (Hedges, 2004). Montgomery McFate, the first anthropologist to serve as the social science director at HTS, linked knowledge of the 'human terrain' with work to counter-IEDs (McFate, 2005b). With the thinking behind HTS put into place, and the right network of military and political elites backing such a project, HTS came into being in the same year as the release of the *Counterinsurgency Field Manual* that was directed by Petraeus (U.S. Army, 2006).

After justifying the HTS concept to the military hierarchy, employees of the U.S. military set about trying to convince anthropologists to support the effort. First, the lead anthropologist advocating HTS, Montgomery McFate, began by asserting that anthropologists could help to remedy the lack of knowledge about 'adversary culture' on the part of soldiers, diplomats, and intelligence agents and thus help prevent any abuses of the people occupied by U.S. forces. This lack of cultural knowledge was the product of "the almost total absence of anthropology within the national-security establishment" (McFate, 2005a: p. 24; 2005c?). (However, according to the Center for Naval Analyses, the U.S. armed forces employed a total of 532 persons with degrees in anthropology (Clinton et al., 2010).) Two of the more basic rationales that were used simultaneously in order to appeal to anthropologists were (1) anthropological knowledge could save lives and (2) by contributing to the military and intelligence apparatuses, anthropologists could exercise influence and help change policy while making their discipline more relevant. However, according to McFate's colleagues in the military, simply providing 'cultural awareness' would not be sufficient: what needed was 'ethnographic intelligence' to penetrate opposing networks on a global scale (see Renzi, 2006: p. 17).

HTS directors and publicists initially claimed that saving lives was the intended outcome and benefit of the program. HTS would reduce the need for 'kinetic' (violent) operations that arose from cultural misunderstandings, while simultaneously providing aid to local communities in an effort to win 'hearts and minds' and thus again reducing the need for violence. The latter were some of the dominant working assumptions utilized by advocates for the program. HTS officials repeatedly emphasized that HTS was not an intelligence program and that HTS personnel did not take part in targeting decisions. HTS deployed human terrain teams consisting of persons who were to have expertise in the Middle East and Afghanistan as well as in ethnographic research, in order to map tribal networks and social structures. HTS officials claimed that there was no substantive conflict between its methods and the AAA's code of ethics: HTTs would seek informed consent from Iraqis and Afghans; those interviewed would not be coerced; and, according to the defenders of the program, identities would be kept confidential.

By 2010, HTS grew in size to include 550 employees (Clinton et al., 2010: p. 76). HTS fielded 10 HTTs in Iraq and 17 more in Afghanistan (Clinton et al., 2010: p. 19). According to recent revelations, HTS received at least $726 million in government funding from 2007 through 2013 (Vanden Brook, 2014). On the battlefield, HTT members could initially earn up to $300 000 annually. In late 2008, however, the program ceased to be run by private military contractors, forcing salaries down to the low $200 000 range. The salaries paid proved to be a significant attraction, especially during a severe recession, as attested to by officials in charge of recruitment (Clinton et al., 2010: p. 89). McFate herself had previously noted that the "majority of newly minted anthropologists brutally compete for a limited number of underpaid university faculty appointments" (2005a: p. 28), thus holding out an alternative. By the middle of 2009, however, only six HTS employees possessed a PhD in anthropology, and four held MAs in anthropology, while most of the HTS staff had degrees in fields unrelated to the stated objectives of the program (Commission on the Engagement of Anthropology with U.S. Security and Intelligence Communities CEAUSSIC, 2009: pp. 13, 63).

The phrase, "controversy plagued the program," was probably one of the media's most frequently repeated statements about HTS (Forte, 2011: p. 150). The program had sprung hundreds of leaks, adding to considerable criticism to the program and attracting more, including from members of Congress that had previously celebrated the program. HTS suffered three fatalities; one HTT member was tried and convicted for the murder of a detainee; and another was arrested on espionage charges. Internal U.S. Army investigations have substantiated reports of waste and fraud in addition to racism and sexual harassment. HTS came under review by the House Armed Services Committee (HASC). During 2013, a rash of U.S. Army documents obtained by *USA Today* were released to the public, along with reports that demonstrated the extreme degree of corruption, mismanagement, and abuses within the program (see Vanden Brook, 2013; Forte, 2013).

Possibly one of the most essential working assumptions of HTS, bordering on a myth, was that US occupation forces, when possessing cultural knowledge, would avoid provoking the resentment of the dominated population and thus increase the chance that those dominated would instead turn against resistance forces and support the US occupation and whatever local government it helped to install. According to Gusterson, this assumption reduced the fight against occupation to a mere cultural misunderstanding (quoted in Udris et al., 2010). Logically, it would also imply that the US invasions and occupations of Afghanistan and Iraq were also the product of cultural misunderstanding on the part of the United States. HTS advocates also claimed that the program would save lives, make war more humane, serve to defeat 'insurgents,' and help to 'anthropologize' the military. On these counts and more, such advocates were not able to stand up to the many, varied criticisms, most of which passed without any official reply from HTS directors who in many

cases refused to answer even basic questions about the program (see Price, 2009a).

Contexts, Conjunctures, and Recursion

While it is logical that both HTS and its critiques first arose within a given context that played a fundamental role in motivating, shaping, and informing their articulation, that context itself consists of multiple historical foundations and more recent conjunctures. First, the immediate context that took shape as a result of the attacks of 11 September 2001 allowed the US political directorate to convert the meaning of the attacks into an opportunity for expanding and reinforcing the national security state and launching ambitious military adventures abroad, both of which (Afghanistan and Iraq) initially drew popular support at home, until the reality of determined resistance set in. This ushered in an "applied reactionary agenda to legitimize and facilitate the active involvement of anthropologists with the US military in the 'war on terrorism' in Iraq, Afghanistan, and beyond" (Sluka, 2010: p. 100). Second, in accordance with the dominant neoliberal program that rose to power in the early 1980s, national security would no longer be the exclusive domain of the state, but would also be outsourced to a growing range of private contractors for whom war was literally business. Third, in order to sustain popular support, and given the history of domestic social strife that arose as a result of the draft for the war against Vietnam, the U.S. military switched to an all-volunteer force, offering numerous incentives and benefits that would not otherwise be available to the 'average' citizen. Fourth, with what are remembered as 'blunders' in Vietnam, Lebanon, and Somalia, the current militarized mass-mediated culture would focus attention on: technological advancements in ordnance and logistics ('smart' bombs and 'precision' airstrikes); better 'knowing the enemy' (during the 1983 invasion of Grenada, US troops lacked local maps, and did not know in advance that English was the local language); and exit strategies and perhaps timelines. In other words, the ethos would be that of winnable wars, and winnable because they were founded on smart thinking. However, other, longer-term foundations had to first be in place for any of the above to take hold so quickly and so firmly.

In terms of the long-term continuities that continue to produce militarization and securitization agendas that focus on foreign targets, this would involve a comprehensive understanding of US history, and the world-systemic history from which it emerged, beginning with the foundation of colonies in the sixteenth century, the conquest of Indigenous populations, the development of nationalist agendas, independence from Britain, the usurpation of territory both Indigenous and Mexican, attempts to annex parts of the Caribbean, and then a wider search for foreign markets – all with corresponding ideological or even theological rationalizations. Ranging from ideas of divine providence and manifest destiny, the idea of an 'American exceptionalism' arose, one that would persist in defying both questions and objections. To veer off the track of foreign intervention would mean being 'isolationist' and it implies a sense of irresponsibility, a formulation that makes sense only in an imperial political culture. Even in the midst of the most brutal wars fought abroad, missionary zeal could readily furnish the justificatory code: it was the responsibility of Americans to teach others how to improve themselves, and the duty of others to obey.

A canonical faith in America as a force for global good became fixed in place and continues to exert some force. Ideas of 'liberating' others from themselves, that is, from their own bad habits of savagery, and from their domestic orders of oppression, became authorized truths of US expansionism and interventionism. In light of both the conjunctures and continuities that are merely sketched here, the content of debates surrounding HTS appear to be reformulating and reinscribing prior histories, practices, and hegemonic ideas of care, protection, progress, the legitimacy of the violence of the mighty, the enlightened and even blessed nature of the dominant, the right to rule and the duty to serve. Had these contexts not been in place, it is difficult to see how the propositions and debates could have arisen, using the intellectual resources that were deployed, and achieving a sense of purposes and outcomes that came with very high stakes.

Institutionalized anthropology in the United States, never wholly insulated from the contexts above, also furnished its own critical parameters and resources that underpinned several critiques, emerging from prior confrontations with the militarization of anthropology in the performance of counterinsurgency. Indeed, the very articulation of the code of ethics officially adopted by the AAA in 1971, which would become central to a large number of the critiques of HTS, came about as a result of the first time that anthropology was used for counterinsurgency, during the Vietnam War years (Fluehr-Lobban, 2003). This first AAA code of ethics strongly condemned secret research and affirmed that the paramount responsibility of anthropologists was to those they study, not their own governments and not their sponsors. Anthropologists were called upon to do "everything in their power to *protect* the physical, social, and psychological welfare" of those they studied (AAA, 1971; emphasis added). That code of ethics "emerged as a direct result of the protest against counterinsurgency research in Vietnam, Project Camelot in Latin America, Project Agile in Thailand, and the Himalayan Border Countries Project in India" (Sluka, 2010: p. 102). In the case of Project Camelot, anthropologists reported that 'for years afterward' the 'aftershocks' of the Project continued to harm their research, "as potential academic collaborators and other interlocutors wondered if they were really working for the CIA" (Gusterson, 2009: p. 48). Thus both the protection of others, and professional self-interest, became prominent features of the earliest ethical critiques of collaboration with the U.S. military in counterinsurgency.

Recursion thus played a role in helping to both substantiate and actualize the main lines of debate the second time that counterinsurgency would be raised to beckon anthropological support, when HTS was launched. If active critics within the AAA had the war experiences of the late 1960s and the 1971 code of ethics to resort to, proponents of HTS made it easier to draw such historical linkages. In the Vietnam War, the Civil Operations and Revolutionary Development Support (CORDS) program involved both propaganda and extreme violence as part of the intended US 'pacification.' Early advocates of HTS hailed it as 'a CORDS for the twenty-first century'

(see Kipp et al., 2006). The authors not only refer to the program in 19 parts of their article, they have significantly revised the history of CORDS to argue that it was actually successful, or potentially so (Kipp et al., 2006: p. 11), without considering its lethal dimension. CORDS gave rise to the Phoenix program in 1967 which, as one of the leading anthropological critics of HTS noted, "led to the capture, torture, and assassination (euphemistically called 'neutralization' by the Pentagon) of tens of thousands of civilians" in Vietnam (González, 2009: pp. 5, 59). Thus, thanks in large part to the advocates of HTS, anthropologists' concerns about the use of ethnographic data for the purposes of intelligence-gathering to support targeted killings once more became paramount with suspicions about the true functions of HTS, masked by its preferred euphemisms. One more instance of recursion resurfaced with González' investigation into the roots of the 'human terrain' concept, which he found dated back to urban policing of inner cities of the United States in the 1960s, specifically directed at quelling the perceived threat of militants of the Black Panther Party, an experience also tied to the FBI's Counter-Intelligence Program (COINTELPRO) aimed at spying on, infiltrating, and destabilizing a wide range of activist groups (González, 2009: pp. 29–29).

This recursion would become salient given two separate events: first, the revelations in the press that the anthropologist who headed the social science directorate of HTS, Montgomery McFate, had worked as corporate spy in infiltrating and undermining various activist groups, including the antigun rights lobby (Corn et al., 2008); and, second, the use of 'human terrain mapping' in a project coordinated between the CIA and the New York City Police Department, and adopted more recently by the Los Angeles Police Department (Apuzzo and Goldman, 2011a,b,c; DGI, 2013; Ruderman, 2012). These revelations would also spur the critique that counterinsurgency is also conducted domestically, even in the 'affective labor' involved in spreading ideas that construct the new 'military normal' in everyday American life (Lutz, 2009: p. 34). Having acknowledged the degree of recursion in these critiques it would be, however, a significant error to assume that the dividing lines in the debates around HTS were instantly formulated with little development and deliberation, or that there was any spontaneous rush to condemn the program (see Forte, 2010).

The Diversity of Critiques and Critics

While many different camps were involved in criticizing HTS, these tend to stand out more in hindsight as few were ever explicit and self-conscious in denominating themselves or precisely articulating their differences. In some cases, selective actors would themselves communicate multiple messages that were sometimes contradictory in terms of their root assumptions or intended outcomes. Critiques of HTS fit into nine areas:

- Organizational: focusing on labor relations and (mis) management within HTS' own ranks (U.S. Army, 2010).
- Financial: focusing primarily on issues of the cost effectiveness of HTS, and criticizing the high salaries paid and instances of fraud. Also included here was recognition of the hard realities of a shortage of full time, if any, academic employment for those with doctorates in anthropology (McFate, 2005a: p. 28), and the resulting heightened anxiety within anthropological ranks.
- Institutional: whether within organized sections of the U.S. military or the AAA, specific actors had their own institutions' interests to defend against HTS. The AAA concluded that HTS was not a valid practice of anthropology. Elements in the military criticized the duplication of functions at higher cost, represented by HTS, as well as criticism of counterinsurgency doctrine, and the skewed budgets that resulted from what military critics viewed as misplaced priorities.
- Professional: these criticisms emphasized the actual or potential harm to anthropology's reputation posed by HTS, the potential jeopardy to anthropological fieldworkers who might be mistakenly associated as U.S. military or intelligence agents, as well as criticizing the perceived low level of professionalism within HTS. In terms of reputation, there was also some criticism of the mainstream media's attempt at creating celebrity status for Montgomery McFate.
- Military strategic: doubts cast about the efficacy of counterinsurgency, its dubious likelihood of success, and the deficiencies of using civilian nonexperts.
- Methodological: critique of the research methods and theoretical models adopted as HTS standards. In particular, these critiques tended to dispute whether Human Terrain Teams actually did anything that could be called ethnography, as well as finding fault with the structural-functionalist models of society and culture present in both the HTS training handbook (HTS, 2008) and in the Army's counterinsurgency Field Manual (US Army, 2006).
- Scholarly: the quality of both the research output and the qualifications of the researchers were the focus of these critiques.
- Ethical: in general terms this involved the passive failure to protect one's informants by neglecting or downplaying a wide variety of basic research procedures regarding informed consent, confidentiality, and 'do no harm.' Indeed, the concern voiced by some critics was that HTS involved the active contribution to doing real harm, charging that HTS served as a 'refined targeting' instrument (CEAUSSIC, 2009: p. 32), while also stressing its other, covert function as a means of gathering intelligence on 'enemies' (Vanden Brook, 2013).
- Political: the broadest and arguably most profound of the critiques tended to place the HTS phenomenon within wider contexts of the militarization of the social sciences, and foreign intervention and occupation. There also tended to be a critical view of 'humane war' and 'humanitarian intervention,' and of avoiding the cul-de-sac of liberal critiques of the liberalism found within justifications for HTS. Political critiques were mindful of the history of U.S. imperialism and the shifting roles of anthropology in that history. This camp also tended to take issue with both the dominance of discussions of professional ethics in critiques of HTS, as well as the conflict of interest presented by military anthropologists in the AAA serving on commissions that passed judgment on both HTS and military anthropology itself.

Despite the wide range of criticism, the debates tended to render prominent only in selective schools of criticism. Critiques were thus dominated primarily by ethical and professional concerns, with some assumptions shared with HTS proponents themselves (see Zehfuss, 2012). There was thus a concomitant concern with the 'tone' of debate, with calls for collegial respect, viewing the stronger expressions of criticism with some distaste as if mere ideological polemics. In that vein, both sides of the debate – HTS advocates and mainstream academic critics, especially military anthropologists – tended to betray shared affinities, a mutual sense of belonging, and common concerns in terms of 'care' and 'protection' of those under the US occupation. There was, in some cases, a shared concern in finding practical solutions (that took occupation as a given, and thus out of bounds as a target of critique) and providing useful advice to military and political authorities. The mainstream media also routinely privileged these voices over others, even though all criticisms were, for the most part, rendered marginal at best (see Price, 2009a).

As suggested above, there were almost as many distinct actors with interests vested in the critique of HTS, as there were distinctive foci of the critiques. In terms of American anthropology, the AAA the Executive Board and the Commission on the Engagement of Anthropology with the U.S. Security and Intelligence Communities (CEAUSSIC) spoke out in terms of professional ethics, while the independent NCA propelled and echoed many of the same ethical concerns, with a few added critiques of military anthropology, counterinsurgency, and occupation. Within the U.S. military, certain agencies and individuals spoke out both privately and publicly, even if only to advance competing forms of human terrain analysis and thus competing for budgetary support for their alternative programs. Within the HTS itself, there were numerous dissatisfied employees, critical former employees, and outspoken defectors who openly exposed the inner workings of HTS (Allison, 2010a,b; Price, 2010). Some of the politically most critical voices, however, were attached to none of the above groupings, opting instead for independent and individual expression of their critiques. Interestingly, anarchist anthropologists generally did not participate in any of the debates surrounding HTS or militarized anthropology more broadly. Those with stakes in the outcomes of the debates were considerably more numerous and varied, ranging from a large array of private defense contractors, to U.S. military officials, the White House, the HASC, and a seemingly endless number of nationalistic military and security think tanks and commentators in the media.

In terms of professional concerns, dealing with the reputation of the discipline and its fieldworkers, the Executive Board of the AAA disapproved of HTS in October 2007, as an "unacceptable application of anthropological expertise," specifically criticizing the program for "placing anthropologists in positions in which their work will be in violation of the AAA Code of Ethics" and threatening the well-being of "both other anthropologists and persons other anthropologists study" (American Anthropological Association Executive Board AAA-EB, 2007). Following a lengthy investigation of HTS, the AAA's Commission (CEAUSSIC) condemned the program in the following terms: "When ethnographic investigation is determined by military missions, not subject to external review, where data collection occurs in the context of war, integrated into the goals of counterinsurgency, and in a potentially coercive environment – all characteristic factors of the HTS concept and its application – it can no longer be considered a legitimate professional exercise of anthropology" (CEAUSSIC, 2009: p. 4). CEAUSSIC emphasized not only "the incompatibility of HTS with disciplinary ethics," but also "the problem of allowing HTS to define the meaning of 'anthropology' within DoD" (CEAUSSIC, 2009: p. 3). The AAA also revised its code of ethics, and in 2009 it reinstated the provisions against secret research.

The shadow cast over American anthropology by the mass-mediated public persona of HTS' lead anthropologist, Montgomery McFate, also spurred further criticisms of the program from the standpoint of professional ethics and professional reputation. In 2008, *Mother Jones* revealed that, prior to joining HTS, McFate had for years worked as a corporate spy, penetrating the antigun lobby and environmental and animal rights activist groups (Corn et al., 2008). McFate was also found to have plagiarized passages in the Army's new *Counterinsurgency Field Manual* (Price, 2007). Price revealed how McFate's doctoral thesis may have made her Irish Republican Army informants vulnerable to cooption and defeat. The thesis includes statements such as "knowledge of the enemy leads to a refinement in knowledge of how best to kill the enemy" (Price, 2009c). Though some anthropologists were concerned about how McFate propagated espionage and unethical practices through her own work, there were particularly strong critiques of McFate's writings on the history of anthropology (see, for example, Lawless, 2009; Sluka, 2010). According to McFate, the discipline had crashed into 'the abyss of postmodernism' since the end of the Vietnam War, which resulted in the "curious and conspicuous lack of anthropology in the national security arena" when the discipline had in the past had a long and 'fruitful' relationship with colonial authority and administration (McFate, 2005a: p. 24).

From Ethics to Politics

Much of the institutionalized defense of the reputation of anthropology revolved around the question of the ethics of research involving human subjects. Ethics for the most part were considered in relation to specific research procedures and immediate relationships, with an emphasis on protection: do no harm, seek informed consent, protect informants' confidentiality, and respects one's obligations to those studied first and foremost. Criticisms of HTS on ethical grounds came from a wide array of anthropologists. The more politically informed approaches argued that it is very difficult to avoid harming other human beings when one is serving one of the primary belligerents in an armed conflict. Others questioned whether informed consent is truly sought and obtained, especially when HTT members travel with armed soldiers and are often themselves armed. HTS members who have sworn that they obtained consent, privately explained that the consent was in written form and that copies were deposited in digital format with HTS, thus creating a trail that could expose their

informants' identities. The U.S. Army itself did much the same, when in posting numerous photos of HTTs in action in Afghanistan, they clearly showed the faces of individuals serving as informants. As summarized in the words of the NCA, "Human Terrain Mapping … does not provide for meaningful informed consent; it endangers those studied; it generates knowledge that will disappear into Pentagon computers; and it increases the likelihood that other anthropologists will be perceived as spies and military operatives, thereby endangering the research, perhaps even the physical safety, of professional colleagues" (NCA, 2007: p. 4).

Anthropologists also directed criticisms at the scholarly and methodological aspects of human terrain research. Many correctly observed that HTS generally failed to deploy people with prior experience in or knowledge about Iraq and Afghanistan, and that most of its personnel lacked any ability to speak local languages. In some cases, HTTs were forced to rely on interpreters in Afghanistan who themselves lacked knowledge of the local language in a given area of operations. The argument that social science can be carried out while forming part of an armed squad was also doubted, even by one Marine commander who observed that, "when you're in uniform you have all the coercive force of the U.S. government" (CEAUSSIC, 2009: p. 50). Indeed, forming part of a patrol, and working while under the watchful eyes of a military escort, dictated the length of the average interview that could be conducted with villagers without coming into the sights of a sniper: 7 min (Allison, 2010a). What counterinsurgency theorist David Kilcullen called 'armed social science' (Packer, 2006) also involved what in the military was known as 'windshield ethnography' (Edwards, 2013: p. 548) that is, high-speed assessments based on immediate impressions and brief, formal interviews, under adverse conditions. Few anthropologists would class this as ethnography. Also questioned was whether academic inquiry can produce the mission-relevant objective facts that were sought, given the simplified structural-functionalist and instrumentalist notion of 'culture' employed by HTS (Zehfuss, 2012: p. 177).

What were arguably the most incisive, far-reaching, and most fertile of the bodies of criticism were those focusing on the political. If furthered, these could have expanded into wider critiques of 'humanitarianism' and 'humane warfare,' as well as critiques of where institutional anthropology's roles stand with regard to the state and the military. Given the primacy of professional reputation, ethics, and scholarship, it was the political critique that still remains to be fully explored. To a significant extent, the political critique emerged out of a contextualized and historicized understanding of how U.S. anthropology came to adopt the ethical statements that it had. Reflecting on the ethics emerging from the Vietnam War experience, for example, on the need to consider the history and interests of those sponsoring research, could lead to a rejection of all research in support of the U.S. military: "On that basis alone – the appalling record of the US military establishment with respect for example to human rights and civilian casualties – any anthropologist who chooses to work for them now can hardly be said to be taking this precaution seriously" (Sluka, 2010: p. 102). Critical anthropologists were particularly mindful then of the '9/11 context' and the 'war on terror' that threatened to quell dissent in US universities (once again) while marshalling teaching and research toward the demands of the national security state.

In addition, the political critique understood the limits sets by an exclusive focus on research ethics and how the latter could dovetail with HTS' self-representation in one key regard: a shared focus on the protection of others. Thus by setting certain common standards beyond which critique was meant to cease, the ethics focus missed the point, such as the broader mission to which HTS contributed. Expressing this argument, cultural anthropologist Price (2009b) explained: "no matter how anthropological contributions ease and make gentle this conquest and occupation, it will not change the larger neocolonial nature of the larger mission; and most anthropologists are troubled to see their discipline embrace such a politically corrupt cause." Moreover, the issue at focus is war as a tool of U.S. foreign policy, rather than finding ways of supposedly 'improving' war (Lutz in Udris et al., 2010).

By 2011, the political critique became as much a critique of the placement of professional ethics at the center of debates with HTS. These critics understood that, "the convenience of a categorical separation of 'the ethical' from 'the political' has left large issues unaddressed" (Price, 2009b) and that the context of the debate is '100% political' (Jackson, 2009). While more ambiguous in the conclusions he drew from this, George Marcus (2009) also observed that, "without the discussion of the political contexts of anthropological research, the discussion of ethics can be formulaic, moralistic, however virtuous, and frankly naïve investing only in terms of established professional imaginaries of practice." Noting the limits of criticisms that suggested that only the involvement of anthropologists in HTS was problematic (thus 'quarantining' the discipline while implying that members of other disciplines should feel unconstrained to participate in HTS), others observed that,

> the separation between politics and ethics is both problematic and futile. It is difficult to see how 'political' questions regarding 'justifications' could be separate from ethics. Indeed, some of the critique framed in terms of professional ethics seems implicitly reliant on a prior judgment about the permissibility of using military force. That is, a wider (or simply different) understanding of ethics influences how the problematic is set up, and whether a war is seen as legitimate. Yet, if anthropologists grant that they might make a contribution to military operations in different circumstances, then their refusal seems not really based on the claimed professional ethics.

Impacts and Consequences

In promoting itself as the smarter way of doing war, HTS advocates initially failed to realize that 'winning hearts and minds' at home (let alone in very different societies) would prove to be a mission never accomplished. This is due to several factors, including the vocal opposition of directors and members of the AAA; the formation of the NCA, whose advocacy rallied attention and support for anthropological opposition to participation in counterinsurgency; declining public support for the wars in Iraq and Afghanistan; and rising discontent within the ranks of HTS itself, finding expression in

numerous damaging leaks previously noted. In personal communications, some individuals who were part of HTS have admitted that the combined efforts of the AAA, NCA, and media had an impact in severely limiting the number of anthropologists willing to join HTS (see also Sluka, 2010: pp. 108–109). The rise to prominence of these debates within anthropology has already begun to make a mark in terms of teaching materials in the discipline, which either devote new sections in revised editions to the HTS debate, or incorporate the works of those directing HTS or who sympathized with it (see Robben and Skuka, 2012; Ferraro, 2009; Erickson and Murphy, 2013).

On the other hand, as outlined in the previous section, there was serious difficulty among critics in moving the debate beyond a matter of disciplinary reputation and professional ethics. All too often discussion was narrowed down to the minutiae of research procedures, or slightly expanded to consider whether HTS was involved in espionage and lethal targeting. The attempt by the AAA's own CEAUSSIC to separate critique of HTS from political concerns was in essence an attempt to depoliticize discussion, which is itself a political act. Also political was the AAA's decision to include a number of military anthropologists in CEAUSSIC, in a situation where their own interests were directly at stake.

One important question was never raised in the debates: whether anthropological knowledge can lend itself to harmful uses. A second was why were anthropologists gathering and publishing such potentially harmful knowledge to begin with? With what appears to be a rapid recession in funding for HTS since 2013, a downsizing in its numbers, and tougher questions from the mass media and former congressional supporters, it might be that such questions will remain unaddressed until the next time something like HTS emerges.

Abstract

Human–computer interaction (HCI) is the study of how people use technological artifacts, and their design. Unified cognitive architectures such as GOMS and Soar, derived from artificial intelligence, have proven useful theoretically, but too detailed for general application in design. The recognition that design flaws had to be identified early in the design process has lead to the idea of user-centered design, with techniques such as QOC supporting the design process, and the development of evaluation methods, such as cognitive walkthroughs and codifications of practical advice in the form of guidelines. To help designers understand why usability problems might have arisen, cognitive psychology theories are being couched as supportive evaluation methods. One such approach, ICS, is an example of a trend away from the dyadic, turn-taking relationship between a single user and a single computer, towards a more complex view of computers as part of our everyday environment. This trend is increasing the involvement of social and organizational theorists. From another perspective, computer scientists see systems as built up from 'interactors' and argue that the user's cognitive processes can be modeled as just another set of interactors. Syndetic models examine the overall system of human and computer interactors. In general, HCI is focusing less on the individual, has a great deal to gain from other social sciences, and has the potential to provide insight into human behavior in return.

The increasing contribution of other disciplines is making human–computer interaction focus less on the individual, with the consequence that a great deal can be gained from other fields within the social sciences, and perhaps, provide more insight into human behavior in return.

Human–computer interaction, more widely known by its acronym HCI, is primarily the study of how people use the complex technological artifacts that now pervade their lives. A secondary, but arguably more important focus, is on how these artifacts can be designed to facilitate this use. As an applied discipline, HCI encompasses theoretical and academic researchers from psychological and computer science backgrounds, who may be interested in the area as a domain within which to apply and evaluate their theories of human or system behavior, as well as designers and engineers from industrial and commercial backgrounds, for whom the pay-off is a saleable product, built faster and more economically than their competitors'. In recent years, with the rapid technological development of computing devices and their increasing ubiquity within telecommunications, the field has expanded to include social and organizational researchers, who examine the impact that the technologies have upon human–human interaction. This itself feeds back to the identification of novel applications and the development of further devices. HCI is now an active, multifaceted, and methodologically diverse component of the domain that it studies, both following and directing technical innovation.

Origins in Human Factors and Cognitive Psychology

The roots of HCI predate the invention of computers, and the term itself has only been used since the 1970s. At their simplest, computers are just machines, built to help people carry out tasks, and the dominant paradigm for studying HCI has been that of ergonomics or human factors, with study of the *interaction* between the human and computer subjugated to that of the human's *use* of the computer. An earlier name for the field was man–machine interaction, and within the field, the words person and human are still generally replaced by the term 'user.' In the same way that early time and motion researchers would analyze the tasks that a factory or office worker performed, breaking their job down into its constituent elements, measuring the time each part took and assessing their relationships to each other to identify any 'wasted,' redundant, or unnecessary actions, so too have HCI researchers attempted to decompose the user's task, and to identify task steps that are difficult to perform, hard to learn, or confusing.

This emphasis on task analytic decomposition reflects the early predominance within HCI of cognitive psychologists, who brought with them information processing models of human thought. These models were themselves based on a metaphor of the mind as a computer: one that received sensory input, processed it with access to memory and inferential resources, and produced motor output to act upon the world. By far the most influential of these within HCI has been the GOMS model (Card et al., 1983), which stands for Goals, Operators, Methods, and Selection. Based upon an intentionally simplistic conception of a model human processor (MHP), a GOMS analysis would identify the goals that the user has to reach, and the operators or mental actions available to the user to carry out the task of reaching the goal. Frequently used series of operators become chunked as easily accessible 'methods' that are linked to a subgoal or specific part of the task, and selection routines enable the user to 'decide' which alternative methods or operators to apply if there is more than one possible route to the goal. The MHP provides estimates of the length of time that executing each basic sensory, cognitive, and motor operator takes (these values being empirically derived from cognitive psychology experiments), and so once an accurate GOMS analysis of the task has been produced, it is possible to sum the durations of each component to produce a prediction of the time taken for the whole task to be

performed. Subsequent elaboration of the approach to allow the perceptual, cognitive, and motor parts of the architecture to operate in parallel, and to model the processing of concurrent activities using critical path analysis, has had notable success in modeling the efficiency of telephone toll and assistance workstations (Gray et al., 1993).

Despite successes such as this, a limitation on the application of GOMS in practice is that it is intended to model only the optimal performance of a skilled user in ideal circumstances, and so it is best suited to industrial-style settings where a particular task may be executed hundreds or thousands of times a day. An interface design that is a second or two quicker to use in these situations will thus result in a large saving in time, and presumably money, for the organization that is paying for it. GOMS is unable to say anything about another crucial aspect of interface use, that is, how long it might take someone to become an expert, how many errors a nonexpert might make, or how pleasant or unpleasant the experience of executing the operations might be. Indeed, the critical assumption within GOMS that operators can be chunked as methods is not actually addressed by the model itself. It remains the job of the analyst to recognize which sequences of operators can be represented as methods, and how finely these methods need to be related hierarchically. Recognizing that this development of knowledge about the task is the key to learning about an interface, Newell (1990) proposed what he termed a unified cognitive architecture specifically to allow problem solving and learning to be modeled as a process of goal decomposition, such that goals are iteratively broken down into subgoals. By specifying the operation of this architecture within a 'programming language' called Soar, Newell provided a technique for predicting the way that users would integrate their postulated initial knowledge with information derived from the computer interface through their interaction with it. In effect, a Soar analyst writes a program in the form of 'If,…Then…' rules, and this is then 'run' to simulate a user's learning behavior.

The GOMS and Soar research communities have had a great deal of influence within the cognitive psychology side of HCI, but as simulation models, their attention to detailed aspects of the interface is both their strength and weakness. While it allows them to identify small but critical aspects of a design as crucial problems for a user, they both require complete specifications of an interface, and for Soar, the task context and information available to a user. They therefore come into their own for the contrastive evaluation of extant alternatives, but are hard to apply systematically at earlier stages of design, when the question is 'how?' rather than 'which?' The same is arguably true of newer, more detailed techniques such as LICAI, which is based on Kintch's construction–integration model of goal formation in text comprehension (Kitajima and Polson, 1997), and EPIC (Kieras and Meyer, 1997). EPIC builds on the model human processor by incorporating many theoretical concepts such as the distinction between declarative and procedural knowledge drawn from Anderson's ACT class of models, and limited capacity visual and auditory working memories coordinated by executive processes. However, as Kieras and Meyer themselves note, 'EPIC was not developed primarily for addressing HCI problems but is a larger scientific endeavor to represent important theoretical concepts of human intelligence or abilities' (Kieras and Meyer, 1997: p. 394).

Development of Usability Evaluation Methods

The apparent concentration of cognitive psychologists on the development of cognitive architectures that would ideally explain all of human behavior, as well as the human use of computers, can justifiably be seen as a problem from the point of view of their colleagues who are involved in the day-to-day design of computer interfaces. It was accepted fairly quickly that full GOMS models were too laborious to be practical, and a simpler (but inevitably less reliable) 'keystroke level model' was developed that avoided the need for a full task analysis. Soar models also require a programming and analysis commitment that can seem disproportionate in the context of design, especially when an apparently small modification in the design requires the whole model to be reprogrammed and rerun. It can also be difficult to identify reasons for the simulated behavior that results from an analysis. These cognitive architectures, then, may prove to be more useful in informing their core disciplines than in practical application.

In reaction to these perceptions of too much cost for too little benefit, a number of 'cut down' usability evaluation methods have been developed. All are to some extent derived from well-founded and principled psychological theories, but by encapsulating key components of the modeling techniques within a process of some form, seek to minimize the overhead costs of learning the theory itself, and to provide a positive cost–benefit trade-off by reducing the need for user trials to be conducted with early prototypes or mock-ups of interfaces (Nielsen and Mack, 1994). Cognitive walkthroughs, for example (Polson et al., 1992), provide a checklist by which aspects of the interface can be compared with the user's notional task, step by step, and screen by screen. The steps of the checklist are in fact derived from cognitive complexity theory, and the method focuses on the semantic appropriateness of the verbal labels or commands used throughout the interface, although the practitioners applying it do not need to know this.

Other approaches seek to avoid any role for theory at all, and base themselves in the codification and reuse of practical experience. From the earliest days of HCI, sets of guidelines have been compiled, both within design teams to provide a 'house style' and in a wider sense as a shared set of 'best practices,' so that designers encountering a problem for the first time have access to the solutions found or attempted by others. Some, such as those presented by Gardiner and Christie (1987), have an empirical basis, and specify specific design features such as acceptable screen color combinations and choices for typefaces. Others are less formal, and direct the designer towards desirable attributes or practices such as aiming for consistency, compatibility and coherence. The rapidly evolving nature of the domain conspires against such stored knowledge, however, for anything designed before the mid-1990s is almost certain to be based on expired technology, whose constraints no longer apply. Concrete prescriptions about design solutions become outdated too quickly for their

promulgation, while the more abstract (such as 'be consistent') have proven too abstract to be of much real use.

HCI and the Design Process

This focus upon evaluation reveals a fundamental problem in early notions of the relationship between design and modeling. An implicit assumption of many HCI approaches was that design could be thought of as a sequential or 'waterfall' process, with discrete stages progressing from a requirements analysis, through specification layers, to implementation, with a final evaluation of the finished product. By locating evaluation at this final stage, HCI staff found themselves limited to what became known as a 'fire-fighting' role, being asked to repair problematic designs at a point when any redesign would result in a product falling behind schedule, further worsening the cost implications of their involvement. Organizationally, it is very difficult to convince people that the design they have been committed to for months has some basic usability flaws.

As Landauer (1995) has pointed out in his econometric analysis of the computer industry, design flaws have to be identified much earlier in design if their identification is to be helpful and cost effective to repair. Fortunately, few designs actually proceed in such a strictly formal manner, with a more serendipitous, parallel, and iterative process being more typical. Such cyclical processes allow HCI contributions to be made at more appropriate junctures, and have lead to an emphasis upon user-centered design (e.g., Norman and Draper, 1986), in which user testing becomes a central aspect of design throughout the process, design itself is directed towards prototyping, and designers are encouraged to 'plan to throw one away,' following Brooks' seminal advice (Brooks, 1975).

A very different approach to providing support to designers in these less structured situations comes in the form of a notational decision support tool called QOC, or questions, options, and criteria (MacLean et al., 1991). Aimed at recording the 'design rationale,' QOC represents the design space through which a product has traveled, listing the questions that the design team were trying to answer at various points, the options that were considered, and the criteria that they used to choose one option over another. By making decisions and trade-offs explicit, and recording the reasons that were cited for making them, QOC provides a mechanism both for managing the decision process and for recording it for later review. It has been found to be particularly helpful in providing background information for people who were not part of the decision at the time, either because they only become involved at a later stage or because they were working on some other part of a large project. QOC is important in that it represents a wider concern with design as a process, rather than simply with evaluating its final products.

Involvement in design at a point before the final product has been created means, inevitably, that HCI methods need to provide advice to designers rather than evaluating finished designs. While 'cut-down' usability inspection methods and heuristic evaluations can be conducted on partial designs and mock-ups, it has been argued that their pragmatic separation from theory weakens their value. While they may well identify problems in a design, the fact that they are not associated with an explanatory theoretical underpinning means that the causes of the problems can remain unexplained. The benefit to the designer of a rapid identification of problems is accompanied by the cost of working out why the problem has occurred and what is to be done about it. May and Barnard (1995) recommended that HCI researchers should work towards providing 'supportive evaluation methods' that assist the designers by accounting for usability problems in terms of some theoretical concepts that are helpful in suggesting redesigns.

They referred to a distinction made by Long (1987) between the 'discovery representation' of a scientific theory and its 'application representations.' The discovery representation allows academics and researchers to explore phenomena, such as typical error patterns in HCI, or the way that users learn about interfaces and solve problems. The application representations, on the other hand, are encapsulations of the theory specifically targeted towards practical application. These may take several different forms, depending upon the intended practitioners and the expected purpose. Unlike cut-down methods, the application representations retain a direct link to the parent theory and, in order to use them, information has to be expressed in theoretically important ways. The advantage for practitioners is that the results of their use is also couched in theoretically relevant forms, and so is linked to an explanatory body of ideas that can be recruited to assist in redesign.

May and Barnard (1995) present the example of a cognitive architecture called interacting cognitive subsystems, or ICS. As a discovery representation, it is unlike GOMS, Soar or EPIC in that it does not seek to simulate cognitive processing, but provides a framework for identifying bottlenecks in the flow of information through a series of cognitive subsystems, each of which is specialized for processing a different level of mental representation. Like the simulation models, these levels include sensory, cognitive, and motor representations. The modeling process involves describing the likely pattern of exchanges between the various levels, the degree of skill-based behavior of relevant aspects of a task, the involvement of the user's recent and longer-term memories, and, crucially, the structure of the user's conceptual task or of perceptual representations of the interface. In this discovery form, the modeling is too complex to be carried out by anyone other than an expert in the theory itself, and the results are couched in terms of the processes and their configuration, rather than specific design consequences.

To support the use of ICS within design, two alternative application representations have been developed: one is a production rule-based 'expert system,' which partly replicates the role of the ICS theorist in constructing a principled model of an interaction; the other is a pencil-and-paper technique for reasoning about the changes over time in the structure of the mental representations encoded at the various ICS subsystems (Barnard and May, 1999). Both of these application representations require some familiarity with the core concepts of ICS, but neither requires practitioners to construct a full ICS model themselves. Their value lies in providing problem-solving tools for designers to apply to partially specified or speculative ideas about interfaces, before any commitment has been made.

Influx of Novel Approaches

In moving away from a simulation of a user interacting with a computer, ICS is part of a trend away from the concentration upon a dyadic, turn-taking relationship between a single user and a single computer. Classical HCI models can be caricatured as having a human issuing commands to a computer, waiting for it to carry them out, and then inspecting the screen while the computer patiently waits for them to form some new goals. While this might have been an appropriate model for HCI in the early 1980s, the advent of distributed computing architectures and the massive interconnection of computing systems over the Internet means that it is inadequate. Even modern personal computers will be carrying out multiple tasks, doing background processing almost in-between each keystroke. The humans are not always isolated users pursuing solitary goals, either, but are using computers as part of their everyday activities, often in social or work settings that involve interacting with other humans with the support of their computers. An analysis of interaction that does not allow for such factors has inevitable flaws.

These developments have led to a new involvement within HCI of social and organizational psychologists, as well as researchers from other social sciences such as ethnomethodology, anthropology, and sociology (Dourish and Button, 1998). This has led to an influx of novel theoretical ideas, in particular Vygotsky's activity theory (e.g., Nardi, 1995) and Suchman's situated action (Suchman, 1987). These ideas re-emphasize the relevance of the context within which human actions are formed, and as Carroll (1997) noted, have brought a continental European perspective into what had previously been a largely North American and British endeavor. Instead of the user and their system, activity theory deals with an 'activity system' composed of social aspects such as attitudes, beliefs, and experiences as well as technological factors.

Another development which moves away from the traditional HCI dyad has come from a computer science perspective, where the idea of a system as a single entity has long been outdated. With the introduction of 'object oriented' ideas, computer scientists have moved towards seeing complex systems as built up from a large number of quasi-independent 'interactors' that exchange information and tasks, with no constraint for these interactors to be part of a single machine. A large body of theory has evolved to model such distributed and concurrent activity, and a logical step has been to see a user's cognitive processes as just another set of interactors. The unit of analysis for such 'syndetic models' (Duke et al., 1999) is the overall system composed of human and computer interactors, and their conjoint activity can be modeled using mathematical formalisms to prove literally that certain interactions can or cannot occur, or that certain assumptions must be met for them to be possible.

Prospects for HCI as a Discipline

Both the social and the computational contributions to HCI currently fall into the discovery mode of analysis, in Dowell and Long's terms, rather than the application mode. It is not yet clear whether these novel directions will crystallize into methods or representations that are directly applicable by design practitioners, or whether they will serve more to direct the commercial development of products away from the classical PC in an office towards other niches. They may also represent the evolution of HCI as a discipline in its own right, with its own methods and theories, rather than as an interdisciplinary area colonized by theories developed in cognitive psychology and artificial intelligence. The tension between academic theorists and practical developers will undoubtedly continue to be a major dynamic upon the field, with its predominance of conference papers enabling nonempirical presentations of novel technologies or design tools to share the limelight with hard-nosed experimental evaluations. In recent years, the increasing theoretical quality of the few specialized HCI journals may provide justification for those who have argued for universities to establish HCI departments in their own right, with their own undergraduate courses. On the other hand, the progressive involvement of computing artifacts within our everyday lives is making their use an ordinary part of human behavior. The increasing contribution of other disciplines is making HCI focus less on the individual, with the consequence that a great deal can be gained from other fields within the social sciences and, perhaps, provide more insight into human behavior in return.

Editor's Note

Research on the human-computer interface has exploded since Turkle's original entry and nearly all of it serves to confirm her prescient conclusion, that "With the computer-human interfaces that researchers project in the near-future, the user will experience the interface as a creature (as in increasingly advanced robots) as prosthetics (a pair of glasses that also serve as a computer screen for mobile net browsing), a piece of clothing (with embedded processors that for example use the temperature of the human body as the input to warm or cool the skin), or as a virtual world that people can fully immerse in and navigate by moving their bodies as one would move in the real physical world." All of these projected future technologies now exist, although some are more developed (and commercially available) than others. Recent sources on human-computer interactions that readers will find useful include: Grudin (2013) and Graimann et al. (2010). The reader's attention is also directed to the International Journal of Human-Computer Interaction, a Taylor and Francis journal where a great deal of new research on the topic appears monthly.

Human–Environment Interactions: Case Studies

CG Knight, Pennsylvania State University, University Park, PA, USA

Abstract

A comparative case study is a research approach to formulate or assess generalizations that extend across multiple cases. The nature of comparative case studies may be explored from the intersection of comparative and case study approaches. Case studies and qualitative comparative analyses share a common explanatory limitation with quantitative models – they suggest reasonable explanations without being able to prove analytic assertions with scientific certainty. Strategies in comparative case studies include research on the basis of community, place, perspective, structure, system, scale, transects, gradients, time, events, analogs, or theory as organizing principles. However, the major organizing principle of a comparative case study often includes others that are subsidiary but inherent in the characteristics of the cases selected. There are no formal rules for evaluating comparative case studies, but reasonable criteria against which studies can be assessed do exist. The intriguing variety of strategies for organizing comparison means that this approach to understanding will continue to be a vital part of human–environment scholarship.

A comparative case study is a research approach to formulate or assess generalizations that extend across multiple cases. The fundamental intent of a comparative case study – development of knowledge – applies equally in the natural and social sciences, with the latter incorporating qualitative analysis in a discursive mode as well as the quantitative and positivist modes of the sciences. Comparative case studies are particularly important to questions of human–environment interaction, combining case study and comparative traditions and thus extending the depth of the individual case study across several instances in time and/or space.

Case Study and Comparative Method

A case study is a rigorous, detailed, spatially bounded, temporally limited description and analysis of an event, process, place, or community intended by the researcher to exemplify a more general insight, principle, or theory. It "is an exploration of a 'bounded system' or case (or multiple cases) over time through detailed, in-depth data collection involving multiple sources of information rich in context" (Creswell, 1997: p. 61). Case studies of particular communities or places are a common and classical mode of analysis in anthropology, human geography, and sociology.

Comparative analysis, in contrast, explores similarities revealed in different situations or cases sharing some common element(s), while differing in others. Comparative analyses are also common among social sciences, varying in the depth to which components are explicated, from statistical abstractions through vignettes to a level of detail common in individual case studies. Often, a case study has unique elements whose effects on the validity of generalizations may be ambiguous or uncertain. Thus, case studies addressed through a conjunction of insights from alternative perspectives will reveal commonalties of particular interest. Comparison between cases can help to delineate such relationships and potentially to clarify ambiguity in a singular case.

Qualitative and Quantitative Aspects

Comparative analyses may proceed via quantitative analysis of numerical abstractions from cases, through detailed narrative description and qualitative analysis. There is no necessary relationship between qualitative and quantitative approaches in case studies and comparative analyses. Qualitative case studies are frequent in anthropology, some schools of sociology, and contemporary cultural geography. Case studies can also be internally as well as comparatively quantitative, particularly in human and economic geography. While comparative studies are often qualitative, they may be quantitative when there are a large number of cases with a small number of variables, as in social survey research.

Explanatory Status of Comparative Case Studies

Both case studies and comparative analyses can be *inductive* or *deductive* (Hempel, 1965; George and Bennett, 2005). However, case studies and qualitative comparative analyses share a common explanatory limitation with models – they are fundamentally *heuristic* rather than *definitive* in that they cannot prove the validity of generalizations beyond providing persuasive evidence in particular contexts (Oreskes et al., 1994). Conversely, a case study illuminating and supporting a general principle does not preclude another case casting doubt. As Leach (1968: p. 344) stated about the comparative method in anthropology, "…comparison…is not, and cannot be, a disguised form of scientific experiment leading to an explanation." Moreover, neither misinterpretation of the case nor failure of the case to illustrate a generalization necessarily means that a hypothesis is not valid. However, a comparative case study approach strengthens the heuristic value of individual cases by bringing in-depth understanding in different circumstances, with greater confidence in the conclusions drawn from them. "The generality of the case study…is relative to the methodological value of the test process involved in the experiment itself and 'holds until proved otherwise'" (Hamel, 1993: p. 40). Multiple cases strengthen the confidence of the researcher that the generality is sound.

Comparative Case Study Strategies

Researchers investigating human–environment issues can avail themselves of many alternative strategies for developing comparative case studies. Strategies included here are certainly not exhaustive or mutually exclusive, but they suggest ways in which comparative case studies can be structured creatively for investigation, presentation, and analysis. Often, the power of the comparative analysis is strongly related to the selected strategy. These strategies include research on the basis of community, place, perspective, structure, system, scale, transects, gradients, time, events, analogs, or theory as organizing principles. In practicality, the major organizing principle of a comparative case study often includes subsidiary dimensions inherent in the nature of the cases selected. For example, selection of case communities along a transect incorporates both community and place perspectives as well, even though the transect is the organizing theme. Examples of each strategy are included in Table 1.

Community

Comparative case studies in disciplines such as sociology and anthropology often focus on studying different social communities to ascertain, for example, generalities surrounding a particular cultural pattern (relations between matrilineal systems and matrilocal residence); social experience (immigrants in the new world city); or community structure (comparative political systems). In human–environment studies, comparison between communities is also important. Examples of such comparative case studies include investigation of traditional or vernacular architecture; studies of pastoral lifestyles and range management strategies; cross-cultural studies of local environmental relations; analysis of ethnic farming populations in the same locale; and studies of traditional navigation technologies and knowledge systems used by island inhabitants.

Place

Places that provide examples of a shared geographical setting or similar human–environmental process may be comparatively studied. Examples include studies of human–environment relations in specific kinds of environment, such as mountains, flood plains, and island or coastal areas; research on societal responses to extreme population density; and investigation of places affected by technological transformation, such as impacts of transportation change (superhighways, dieselization of railroads), agricultural mechanization leading to rural depopulation, management of water resources, and transitions in household energy use in developing countries.

Perspective

An alternative to selection of different cases analyzed from a similar perspective is to bring multiple perspectives to a single case. Such an approach explicitly invokes a multioperationism desirable in all case studies – the convergence of different kinds of evidence toward a more complete and rich understanding. One common method for an approach based on perspective is the *emic* versus *etic* familiar from anthropology – the understanding held by the individuals involved, in contrast to the analytical viewpoint of the researcher. This distinction is now an important element of postmodern qualitative inquiry across the social sciences. The use of perspective in comparative study includes landscape analysis, analysis of environmental controversy, and multiperspective community or place studies.

Structure

Comparative case studies may be developed on the proposition that selected cases reflect the functioning of a common underlying structure, somewhat analogous to comparative linguistics. For cross-cultural translation of color terms, a formal Munsell color chart can provide a common structure on which to map various language terms for color. Less formally, comparative analysis may be based on typologies that provide the framework for comparison. In the human–environment realm, structural frameworks used as the basis for comparative case studies include Linnaean plant classification compared to indigenous ethnobotanical plant classification, fundamental requisites of a society, comparative farming systems, and human response systems in the face of natural hazards.

System–Subsystem

A comparative case study may be organized to look at various levels of a complex system to establish relationships,

mechanisms, and emergent properties that vary by the level under investigation. Examples include studies of the public role in environmental management at local, state, and national levels; studies of agricultural change viewed at the family, village, society, and regional levels; and studies of the driving forces of deforestation, from family- and farm-level decisions, through regional and national forces to the global economy.

Scale Analysis

Case studies of the occurrence of phenomena at different spatial scales may be undertaken to ascertain variance or invariance of form or process. Scale analysis has become an important element in the study of the natural environment, including hydrological, climatological, and ecological systems. In human–environment investigations, scale analysis is undertaken in studies of the causes and potential impact of climate change to suggest local and larger scale determinants of greenhouse gas emissions; appropriate levels of generalization of impacts, such as climate change on farming; and initiatives for mitigation.

Transects

Geographical transects provide one kind of spatial sampling that researchers can use to develop information and insight that can be generalized across a society or region. A transect provides one means of minimizing sample bias in an attempt to develop generalizations and analysis of differences within a society or region that might reasonably be assumed to be homogeneous. Such studies include investigation of market towns along a transect in an agricultural region; research on the dynamics of colonist settlement along new roads in rain forest areas; or exploratory archeological investigation of settlement remains in a region. In transect studies, the area being investigated may be found not to be homogeneous, suggesting comparative study of social differences (such as ethnic enclaves in an agricultural region) or environmental differences (such as local availability of ground water in the High Plains of the United States). One special kind of transect selected in recognition of difference rather than homogeneity is the gradient.

Gradients

Cultural ecologists in geography and anthropology often undertake comparative case study analyses using sample cases selected across environmental, spatial, or social gradients rather than in areas representative of a homogeneous area. One principle underlying such studies is that society adapts to environmental differences; thus the purpose of study is to understand the nature of adaptations and how they function in the face of environmental change. Examples include studies of agricultural adaptation along an altitudinal or climatic gradient; investigation of the impact of proximity on market involvement in a developing country; or research on the human–environment interactions in different societies occupying similar environments, either across a social gradient within a similar environmental region, such as farmers in Africa, or living interspersed in the same location, such as pastoralist and agriculturalist land use management.

Time

A temporal approach to comparative case study examines the same place at different times, different places at the same time that reflect temporal differences, or different places at different times. In the first approach, a single place is examined at different times. Such a study might show the development of successive human–environment relations as population or other variables change through time. When a geographical location was occupied by different societies through time, such studies in geography were offered as evidence of 'sequent occupance (sic),' one of the strategies used to refute environmental determinism. Investigation of different places at the same time could be seen as a quasitemporal process when diffusion of an innovation or process of change is spreading geographically and some areas represent an older core location with earlier adaptation, while others represent preadaptation or emerging stages. An example might be the diffusion of a cash-cropping complex in a traditional rural society where various locations along a space–time gradient represent stages of adaptation of a new technology.

Events

In the evolution of comparative case study in the human–environment realm, one salient mode of analysis focused on human response to natural hazards. Natural hazards research sought commonalties, first, in human response to floods, followed by attention to other natural hazards, to the hazardousness of places, and eventually to technological hazards. In all of these realms, comparative case studies provided the core strategy for the development of general frameworks for natural hazard analysis. Seen more generally, selection of hazard case studies for comparative research may be organized around extreme geophysical events, such as tornadoes, hurricanes, and floods, or long-term environmental threats such as drought, deforestation, or soil depletion and erosion. Comparison was also based on spatial dimensionality and temporal occurrence of hazards, as well as on hazard geometry. The event-based approach can be extended to other kinds of events: human and ecological impacts of dams; local resistance to imposed political or technological change; or suburban sprawl.

Analogs

An analog is based on the premise that objects or events having some similarity may also have other similarities. Thinking by analogy, in fact, underlies the comparative case study approach, in that the similarity among cases makes them, in fact, analogous in some respect. As a formal organizing principle, analogs inherently involve two or more cases that share sufficient commonalty that insight can be gained by comparison. There is no formal procedure for developing analogs; rather, good analogies depend on "pragmatic considerations regarding contexts, interests and purposes" (Jamieson, 1988: p. 81) and represent a priori insight before the full development of the comparative cases. In comparative case study using analogs,

there is no necessary juxtaposition of the cases in time or space; rather, comparison originated in a conceptual linkage that appeared promising to the researcher. Analogous case studies are strengthened when they are selected with explicit similarity criteria.

Comparative case studies developed within an analog framework include studies of the impact of modern technology in developing countries; society's response to acid rain, ozone depletion, and future greenhouse gas stabilization; responses to past climate change; and adaptation to drought. Often, comparative case studies built upon analogs are oriented to the future, asking whether insights gained from the analogs can be applied to new decisions.

Theory

Comparative case studies can address theory, wherein the cases are selected to test hypotheses from the theory. Examples include comparative case studies of the process of agricultural change with respect to population growth, such as the Boserup hypothesis; modeling society's progress through economic, demographic, disease, or mobility transitions; testing Wittfogel's concept of the hydraulic civilization; or explicating a framework for understanding the processes of environmental adaptation. In such studies, individual cases are not only compared with other empirical cases, but compared also with the expectations from a priori theory.

The Comparative Case Study Method

The comparative case study approach draws upon the same kinds of method that are common to the case study and comparative methods. The researcher links a hypothesis to certain cases using one or more of the strategies described previously, gathers information about the cases, develops evidence from the cases, presents the cases, and constructs explanation or generalization from the evidence. Insight, creativity, intuition, and even serendipity cannot be dismissed as important elements that the researcher uses to formulate hypotheses and to develop the strategy of research.

The depth of analysis of the constituent cases in a comparative study selected for *instrumental* purposes may not be equivalent to that of an individual case examined for its *intrinsic* interest (Creswell, 1997). Focus on an issue or hypothesis draws attention to specific relevant issues or variables in the cases. Yin (1989) referred to this difference as *holistic* versus *embedded* analysis, the latter connoting the selection of cases within a wider research question.

Tools for Analysis

Researchers developing new case studies for comparative analysis have a wide variety of available tools and data sources, including interviews, surveys, participant observation, ethnographic research, field observation, officially collected information, archival research, environmental analysis, remote sensing, qualitative analysis, quantitative analysis, systems analysis, structural analysis, and various modes of modeling. In contrast, researchers undertaking meta-analysis of previous studies may be confined to information developed through other researchers' selection of tools and information; the researcher may undertake further study to amplify information on the case. As with individual case studies, the results of comparative analyses are usually narrative, although normative, probabilistic, statistical, simulation, or graphic models are possible modes of conceptualizing and communicating research outcomes.

Evaluation of Comparative Case Studies

Although there are no formal rules for evaluating comparative case studies, there exist reasonable criteria against which studies can be assessed. These include establishing the relevance of the cases; thorough identification and consultation of information sources; the adequacy and accuracy of reflecting information from sources; correct interpretation of sources; objectivity in reporting and interpretation; and internal consistency as evidenced by triangulation or multioperationism. If the cases purport to be a 'natural' experiment, controls provide an important strengthening of the argument. Additional criteria include the possibility of replication; reporting of contrary evidence and/or interpretation; specification of exceptions and special circumstances; recognition of and explanation for contrary cases; rigor versus superficiality; and value-added insight and understanding. Primary case studies must also meet the canons of field or archival work in the relevant discipline; comparative case studies built from meta-analysis of previously published work have potential for review by original researchers.

Conclusion

Comparative case studies offer a richness of insight that may be lost in the abstractions of statistical analysis, while maintaining the tradition of the case study as a means to explore generalities in the complexity of the real world. The intriguing variety of strategies for organizing comparison means that this approach to understanding human relationships to the environment will continue to be a vital part of human–environment scholarship.

Abstract

David Hume played a major role in the founding of the social and behavioral sciences in the Scottish eighteenth-century Enlightenment. The article discusses his general psychological and philosophical principles, his skepticism, his contributions to moral and political theory, to economics and politics, to history and historiography, and to the philosophical, psychological, and sociological study of religion.

David Hume, a leading figure in the Scottish Enlightenment, contributed significantly to the disciplines of psychology, history, political science, and economics, as well as to more theoretical discussions in ethics, aesthetics, epistemology, and philosophy of religion. He was a controversial figure in his own day because of his criticisms of both natural and revealed religion, and because of the political opinions he expressed in his popular political essays and his very successful *History of England*. His skeptical arguments concerning induction are still discussed today by philosophers interested in probability theory, and his account of the foundations of morality enters into current disputes about the nature of moral judgment.

Life and Writings

Hume was born in Edinburgh on 26 April 1711. The family was of genteel but modest means: His father, Joseph Home, an advocate and member of the minor gentry of Scotland, died when he was 2 years old; and his mother Katherine, who never remarried, raised him, his sister, and older brother on their small estate of Ninewells on the Scottish Borders. Hume probably began taking classes at Edinburgh University in 1721 where he studied Greek and Latin, scholastic logic and metaphysics, natural philosophy, and took an extramural class in mathematics. There is no record of his ever having taken a degree (which was not unusual at this period) and, in a short autobiography written just before his death, he noted that, while his family intended that he study law, his own interests were in "Philosophy and general Learning." He stated that he planned his first philosophical work, *A Treatise of Human Nature*, before he left University, probably in 1725 or 1726, and from his correspondence we learn that he began struggling to write about psychological phenomena in 1727.

Suffering from complaints that we would now consider to be largely psychosomatic, Hume decided in 1734 that he needed to pursue a more active life; he left Scotland for Bristol where he worked briefly for a sugar merchant. After a few months, he went to France where he spent the next 3 years writing and studying. He first went to Reims, but soon settled at La Flèche in Anjou, in the vicinity of the famous Jesuit college where more than a 100 years earlier René Descartes had been a student. The first two books of his *Treatise of Human Nature* ("Of the Understanding" and "Of the Passions") were published in February of 1739 over a year after he returned to England, and the third ("Of Morals") was published 21 months later, after he returned to Scotland. In his autobiography Hume claims that the *Treatise*, from which he hoped to gain literary fame, "fell dead-born from press"; however, there is evidence that it did make a stir among the Edinburgh literati, and it has been taken by scholars since that time as Hume's most important and seminal work. It was followed in 1741–42 by his very successful *Essays, Moral and Political*, written to reach a more popular audience.

Hume unsuccessfully applied for university chairs at Edinburgh University in 1744–45 and at the University of Glasgow in 1751–52, where he had strong support from his friends (including Adam Smith and physician William Cullen) but was opposed by many of the clergy who accused him of irreligion. While his *Treatise* contained no explicit discussions of religion, this was changed in his rewriting of its first book, which was published under the name of *Philosophical Essays Concerning Human Understanding* in 1748. It contained his famous argument against rational belief in testimony for miracles, as well as the basis for his later attack on the design argument for the existence of God. Continuing to search for a career, Hume spent some time during this period as Secretary to General St Clair and participated in a rather futile attack in 1746 on the coast of Brittany during the War of Austrian Succession. In 1747, he traveled with the General as his aide-de-camp on a Military embassy to the capitals of Britain's allies Austria and Sardinia.

In 1749, Hume returned once more to Scotland and began an immensely productive decade in which he became one of the leading British writers of the day. In 1751, he moved from Ninewells to Edinburgh where he was to live for much of the rest of his life as a member of what has become known as the Scottish Enlightenment. In 1751, he was the elected secretary of the Philosophical Society of Edinburgh, the forerunner of the Royal Society of Edinburgh, a group devoted to the study of natural science, medicine, and technology. (He was later, in 1762, to present Benjamin Franklin's paper describing the use of lightning rods to the Society.) In 1751, he also published his *Enquiry Concerning the Principles of Morals*, a reworking of the third book of his *Treatise of Human Nature*. His correspondence at this time also indicates that he had already written substantial portions of his posthumously published *Dialogues Concerning Natural Religion*. In 1752, Hume published his popular *Political Discourses*, which included important essays on economics, and began work on what was to become his most successful piece of writing, namely, his multivolume *History of*

 http://dx.doi.org/10.1016/B978-0-08-097086-8.61055-3

England. He became Keeper of the Advocates Library (later incorporated into the National Library of Scotland) in January, which gave him direct access to a large collection of historical sources. The first volume of the *History*, concerned with the reign of James I and Charles I, was published in 1754 and the remaining volumes between 1756 and 1761. In 1758, Hume published *Four Dissertations*, which included his "Natural History of Religion," "Of the Passions" (a reworking of the second book of the *Treatise*), "Of Tragedy," and "Of the Standard of Taste."

In 1763, after the end of the Seven Years' War, Hume was invited to go to France as Secretary to the Ambassador, Lord Hertford. In France, where his writings were admired, he was lionized both by the mighty and by the intellectuals. He developed close relations with many of the *philosophes*, especially d'Alembert. Hume was *Chargé d'affaires* for about 4 months in 1765 after Hertford left Paris. He returned to England at the beginning of 1766 bringing with him Jean Jacques Rousseau, on the advice of his Parisian friends; Rousseau sought refuge in England from persecution on the Continent. Hume and other British friends procured a pension for him from the King. However, this whole affair turned into a disaster as a result of Rousseau's paranoia. Rousseau denounced Hume as his enemy. Hume's defense of his own conduct was published by d'Alembert and Suard in Paris in October of 1766. His last public appointment was as an Undersecretary of State from February 1767 to January 1768. He retired to Edinburgh where he continued to publish corrected editions of his writings – that is, all but the *Treatise* which he publicly disowned in 1772 in favor of his later philosophical writings including the two *Enquiries*, *A Dissertation on the Passions*, and his *Natural History of Religion*. Hume died on 25 August 1776 as one of Britain's foremost men of letters.

General Philosophical and Psychological Principles

In his *Treatise of Human Nature*, Hume set out to provide a foundation for all the sciences – natural as well as social – on a science of human nature. The central principle of that science was the association of ideas which, Hume wrote, 'enters into all his reasonings.' He held that ideas are associated through resemblance, contiguity in space and time, and causality. He wrote that these three modes of association "are the only links that bind the parts of the universe together, or connect us with any person or object exterior to ourselves." Mental energy – what he called 'force and vivacity' – is transferred via the associational links from one perception to the related ones. This theory played a central role in his account of the source of our inductive reasoning processes and our natural common sense belief in reality in his theory in Book 1, "Of the Understanding," in his theory of the indirect passions in Book 2, "Of the Passions," and in the account of sympathy which forms the basis of the theory "Of Morals" which he developed in Book 3. Hume attributed the association of ideas to the faculty of imagination, and contrasted its conclusions with those based on reason and the senses.

Hume saw himself as following the lead of recent British philosophers including Locke and Hutcheson who had begun to apply to the human sciences the experimental method that had proved so successful in the physical sciences. However, he argued that, unlike the physical sciences, it is impossible to carry out controlled experiments in the science of human nature because introspection interferes with the natural principles it seeks to discover. Rather, he argued that the human sciences must base their principles on the observation of human behavior. Many of his inferences were drawn from his vast knowledge of history, though in Book 2 of the *Treatise* he considered the way different psychological effects result from different social situations.

In his discussion "Of the Understanding" in Book 1 of the *Treatise*, Hume followed Locke in arguing that all our ideas are derived from experience, that is, from the *impressions* of sensation and reflection. In Hume's hands, this principle led to a deep skepticism; he argued that our most natural beliefs concerning the nature of space and time, the existence of a world independent of our senses, of a single self which lasts throughout our lives, and of objective causal power cannot be derived through reason. Rather, these beliefs have their source in 'fictions' or 'illusions' generated by the imagination and the association of ideas.

Scholars still disagree about the nature of Hume's own basic philosophical commitments. Some, following the logical positivists, hold that Hume rejected all metaphysical claims, including the claim that there are unknown powers in the natural world, which are independent of human understanding. For these interpreters, his principle that all ideas are derived from impressions, trumps the fictions produced by the imagination. Others regard this 'copy principle' only as a source of the extreme or Pyrrhonian skepticism that he described so vividly in the conclusion to Book 1 of his *Treatise*. They note that he himself maintains what he called 'a mitigated skepticism, or Academical philosophy' in response to his own and other's Pyrrhonian arguments. According to the mitigated skepticism that he adopted at the end of his *Enquiry Concerning Human Understanding*, "philosophical decisions are nothing but the reflections of common life methodized and corrected." On this reading, natural instinctive beliefs, guided by the principles of the association of ideas, provide Hume with what he called 'a legitimate Ground of Assent.' These natural beliefs gain legitimacy from their universality and the fact that they are necessary for human survival. The overall aim of Book 1 of his *Treatise* and his first *Enquiry* was to show the narrow limits of our human understanding, and the way that the natural processes of the imagination are required to give us a purchase on reality.

While he used induction in his own science of human nature, Hume argued that induction is not itself founded in reason, but has its source in custom and habit. From our past experience of the constant conjunction of one kind of event followed by another we infer like events in the future. But this inference itself presupposes the principle of the uniformity of nature. Hume argues that any claim to justify *this* principle by past experience would be circular, and that it is impossible to demonstrate that the laws of nature will continue in the future as they have in the past. He concludes that the inference from past regularities to future events, even in experimental science, is not founded on reason but on 'an instinct or mechanical tendency,' which we share with other animals.

Hume extended his claim that nothing but constant experience makes us ascribe causal necessity to human actions.

He argued against those who claim that while physical events are necessitated by their causes, the human will is free. He noted that while we have a false sense of liberty when we reflect on our own actions, we clearly accept necessity when we consider the actions of others. We recognize that their actions are regular, and can generally be inferred from their motives, character, and circumstances. Thus, he argued, there is just as much evidence of necessity in human actions as in physical events, and in both cases a scientifically-minded-person will assume necessity even when the regularity is not apparent. Hume argued further that we assume necessity in holding persons responsible for their actions. Punishment and reward are only justified if actions flow from established character traits, not from random actions. It is only if intentional actions are determined by something fixed and durable in a person's character that they are the proper subjects of praise and blame, and of moral responsibility.

Moral and Political Theory

In Book 3 of his *Treatise of Human Nature ("Of Morals")*, Hume followed Francis Hutcheson in arguing that our moral judgments are at bottom based on sentiment rather than reason. But he differed from Hutcheson in arguing that it is our *sympathy* with the pleasure and pains of others, rather than an innate moral sense, which forms the basis of our moral judgments. While he argued that there are no objective moral facts, Hume stressed in his *Enquiry Concerning the Principles of Morals* that before we can arrive at a correct moral judgment we need to employ our reason in making careful distinctions, comparing different situations, and determining general facts.

He distinguished between *natural* virtues such as benevolence, love of children, and pity for the unfortunate, and *artificial* virtues such as adherence to rules of ownership of property, promise keeping, and allegiance. While we have a natural motivation to be benevolent, the artificial virtues depend on the development of social conventions. Hume argued that these virtues are valued merely because of their utility for the maintenance of society – a claim he subsequently extended to the most important natural virtues.

Hume begins his account of the origin of justice in the *Treatise* by focusing on the development of the conventions of private property. Such conventions become necessary because of the selfishness and limited generosity inherent in human nature and the instability and scarcity of external goods. Hume argues that men have an unquenchable desire to gain more and more goods for themselves and their families, and that it is this desire more than any other passion which is directly destructive of society. Like Hobbes before him, he postulates a state of nature that is 'full of war, violence, and injustice.' While, like Hobbes, he thinks that a solution must come from 'judgment and understanding' rather than the passions, he argued that these faculties operate in an unexceptional way according to the principles he laid down in Book 1 of the *Treatise*. A convention or agreement to refrain from the goods of others "arises gradually, and acquires force by a slow progress, and our repeated experience of the inconveniences of transgressing it." It is through custom and habit that we develop a convention for the orderly transference of goods through mutual consent. Thus, while promoting their own self-interest men develop "a general sense of common interest … which induces them to regulate their conduct by certain rules" for the stability of possessions. It is this common interest or *utility* which forms the basis of the moral value we ascribe to those who follow these rules in an established society.

But while *utility* accounts for the need for general rules for the possession and transfer of property and performance of contracts, Hume argues that specific rules determining the right of property must be based on nonrational principles of the imagination, or the association of ideas. Thus, for example, the ascription of property to the first possessor, while not more useful than giving it to the person who will improve it, is adopted because the mind moves naturally from the object to what is contiguous. Again, the imagination favors the rule of inheritance from parent to child, given the causal relation between them. While he rejects any natural right to what one has mixed one's labor with, Hume still argues that the imagination will favor that relation because of the association of the cause (the work of the laborer) with the effects (the change in the object on which the labor is applied). But this can only be one of a variety of principles which determine the positive law for the possession and transfer of property, and the balance between these various rules can only be established by custom and opinion.

Hume presented a parallel account of the origin of government, and the virtue of allegiance to it once it is established. The necessity of rulers would have become apparent as soon as human beings began to live in large impersonal societies where they were naturally inclined to seek short-term gain without considering their long-range interest in maintaining the rules for the stability of property. Reason suggests the solution of accepting magistrates who enforce the rules of justice and punish offenders impartially. But again, on Hume's account this solution developed gradually: men first gave their allegiance to leaders in war when threatened by a common enemy, and those leaders and successors became their rulers.

Hume opposed the Lockean or Whig theory that allegiance was based on a promise made in an original contract. He pointed out that there was no historical evidence for such a contract, that promises themselves require a convention as much as government, and that popular opinion gives no credence to such an opinion, except in Britain where it was inculcated by Whig party politics. But while he opposed the Whig theory, he agreed that government can only persist with the acquiescence of the governed – and not simply by force. For Hume, this acquiescence is maintained by custom and opinion, and he wrote that governments whether monarchical or democratic 'are equally legal, if established by custom or authority.' Hume was equally opposed to the Tory theory of "Passive Obedience" which was based on a theory of Divine right and that active resistance to the established government was never justified. He recognized that when government no longer serves the interests for which it was formed 'the obligation to obedience must cease.' What then results is what he called an 'appeal to heaven, that is, by war and violence.' However, violent revolution can only be 'the last refuge in desperate cases.'

While the general necessity of allegiance is based on its utility for the public good and that of each subject, Hume held

that this necessity did not solve the problem of determining who had the right to govern – a problem which was still an issue in Britain in his own day. He held that there was no rational solution, but that the imagination suggested several which had been adopted historically when succession was in question – including long possession, present possession, conquest, family succession, and positive law. He pointed out that while the last of these proves the best solution, even it depends on accepted custom and opinion. He argued that given the heavy costs of civil war and that a constant threat of rebellion would encourage authoritarian government, habits of obedience are necessary in any political society.

Economics and Politics

Hume was an important forerunner of classical liberal economic theory. His friend Adam Smith noted that Hume was the first to argue that economic forces determine political structures rather than vice versa and that the development of modern liberty and government by law was due to the development of trade and industry. Hume saw in the rise of the merchant and manufacturing classes a check to the despotism that existed in premodern society. He argued that it was the interest of these classes to live by equal laws and to limit the power of both the aristocracy and monarchy. His analysis was based on comparisons of the governments of modern Europe with those of the ancient and medieval worlds, as well as the rise of parliament in the early seventeenth century that led to the English Civil War. While he accepted James Harrington's social determinism, his originality lay in the postulation of commercialism as the key factor limiting the absolute power of the monarch.

Developing the ideas of Bernard Mandeville, Hume opposed those in his day who held that the creation and consumption of luxury goods enfeeble both the individual and the state as a whole. Hume argued that the increase and consumption of commodities 'which serve the ornament and pleasure of life, are advantageous to society,' and that a consumer society encourages the development of hard-working persons whose labor can easily be turned to the service of the state in times of national need.

Hume regarded economic behavior as deeply rooted in human psychology. He argued that human beings have an insatiable desire for activity, and that there is nothing that satisfies this desire more than lucrative employment. There is, he argued, no pleasure which feeds on itself so much as that of the merchant who sees his fortune grow. The habit of industry stimulated by desire for this pleasure creates a frugality which does not naturally exist in an agrarian society based on inherited wealth. The love of gain, which marks the activity of the merchant, results in large sums of money that can be lent at low interest to stimulate further economic growth.

In his essay "That Politics may be reduced to a Science," Hume stated that while individual human actions are often unpredictable, politics, which studies the effects of laws and constitutions can arrive at generalizations through experience which approach the certainty of mathematics. He argued, for example, that nonrepresentative democracy inevitably degenerates into anarchy and eventually to despotism – as happened in ancient Athens and at the end of the Roman Republic. However, he also saw the danger of generalizing from limited historical experience, as he thought Machiavelli had done in drawing conclusions about the instability of monarchical forms of government from 'the furious and tyrannical governments of ancient times' and the small principalities of Renaissance Italy. Hume noted that Machiavelli's principles had been proved false by the experience of the large European hereditary monarchies of the seventeenth and eighteenth centuries. While he himself put forward generalizations concerning different forms of government, his skepticism led him to recognize that these would need to be modified by future circumstances that had not yet existed in human history.

Hume was a critic of the civic humanist tradition that held that good government must be based on the virtue of politicians. He argued that good constitutions must recognize that human beings are predominantly self-interested. He recognized three forms of legitimate government in the eighteenth-century world in which he lived – republics such as that of the Netherlands, civilized monarchies such as France, and the mixed form of government of Britain which, he thought, tended more toward the republican form because of the independence of parliament and the separation of powers. Each form of government promoted rule by law, as opposed to rule by the arbitrary discretion of the monarch, and in each there was an inevitable struggle between authority and liberty. The danger of civilized monarchy such as existed in France lay in the heavy burden of taxes on the land which impoverished the peasants, as well as creating a dangerous inequality which weakened the overall power of the state. But Hume also saw a potential instability in the republican and mixed forms of government of the Netherlands and Britain that relied on public debt to finance the interests of the state. Nevertheless, he favored the latter forms of government since they encouraged commerce and equal distribution of wealth. Hume wrote that equality "diminishes much less from the *happiness* of the rich than it adds to that of the poor" while at the same time it "augments *the power of the state*."

While he was an early supporter of American independence, the "Wilkes and Liberty" riots of the late 1760s and early 1770s convinced him that the balance of power in Britain had shifted too much in favor of liberty. This and other statements in his later life have led some scholars to consider him a supporter of counter-revolution and a forerunner of the conservatism of Edmund Burke.

Historiography and History

Hume was both a philosopher of history and a philosophical historian. He both articulated and applied principles for the assessment of historical sources. These principles are carefully laid out in his essay "Of Miracles" where he discusses the criteria we ought to use to judge the reliability of witnesses, as well as the need to balance those results against the intrinsic likelihood of the occurrence of the event. Following discussions of 'probability' in John Locke and other early modern writers, he formulated criteria for the reliability of written and oral testimony: these included considerations such as consistency of different reports of the event, the character and expertise of the witnesses, their number, and their self-interest

in convincing others of their accounts of actions and events. Hume held that we need to balance these considerations of the reliability of testimony against the absolute likelihood of the occurrence of a miracle. Given that a miracle is defined as a violation of a law of nature and the existence of such a law is determined on the basis of an invariable experience, there is extremely strong evidence against the existence of any miracle. He argues that no historical testimony of a miracle has succeeded in overtopping the negative evidence that arises from the very nature of the claim that a miracle exists.

More generally, Hume argues that we must balance the testimony given by historical witnesses against the inherent probability of the occurrence of any event. In his essay "Of the Populousness of Ancient Nations," a major pre-Malthusian demographic study, he challenged the commonly held view, based on the writings of ancient historians, that the ancient world was more heavily populated than modern Europe. He supported his argument on a number of grounds including the lack of opportunity of ancient slave populations to reproduce, on the destructiveness of ancient wars, and on the unlikelihood that ancient economies could support vast populations. In his *History of England*, Hume also frequently appealed to general principles of human nature, those which he believed to be established by the newly emerging human sciences, to evaluate the credibility of his historical sources.

Hume sought to write an impartial *History of England* which favored neither Whigs nor Tories, though, in his own day, it was criticized by both. He also broke with those who wrote histories from a religious perspective, seeing either the hand of providence in the affairs of men or the world as degenerating from a golden age. His aim was to write a history which recognized advances in civilization where they occurred, but also recognized the tenuous nature of human progress which was constantly under threat of relapsing into barbarism.

In the *History*, Hume charted the vast changes in the English constitution from the *Magna Carta* to the Revolution of 1688, and the overthrow of James II. His *History* was controversial in his own day because he argued that there was 'no regular plan of liberty' before the reign of the first two Stuart kings, when Parliament began to act independently of the monarch. On Hume's account, the reign of the Tutor monarchs including Elizabeth I was despotic, and that the country did not make any significant economic or political progress until the first half of the seventeenth century.

Hume held that there are a variety of causes that contribute to historical change. As already mentioned, he considered the rise of a middle class as playing a major role in the development of English liberty. He also took account of the unintended consequences of historical actors. While the religious fanaticism of the Puritans led to the execution of Charles I in 1649 and the dictatorship of Cromwell during the Commonwealth period, its ultimate result was the 'mixed form of government' on which English liberty was established. His moral praise was always for those who after 1642, whether supporters of the king or parliament, favored the balance of power. This led Hume to 'shed a generous tear for Charles I' who he believed had honestly supported limiting the power of the monarchy after 1642, but also led Hume to condemn the actions of James II in the 1680s because he violated what had by then become the established constitution.

Religion

Hume was a major Enlightenment critic of religion – particularly of monotheism, which he considered inherently intolerant and subversive of morality. In his *Natural History of Religion*, he argued that religion has its primary roots in our fear of the unknown forces that affect life and death, as well as our natural tendency to think of those forces in humanlike terms. Since these forces affect us in arbitrary ways, we seek to placate them as we would human tyrants, through praise and debasement of ourselves. This, he argued, is particularly true of monotheistic religions, where the single deity is thought of as infinitely more powerful than humans. Debasing actions such as fasting or self-punishment are performed to please such a deity – not moral actions which, according to Hume's own philosophy, have their basis in our sympathy with the pain and pleasure of our fellow humans. Hume explained the intolerance of Christian sects to one another as arising from their reasoning that a single God would not allow different rituals and beliefs to His devotees. Polytheists, on the other hand, can easily accept their neighbors' worship of different gods, are willing to incorporate them into their own pantheon and adopt their practices. He attributed intolerance to "almost all religions, which have maintained the unity of God."

Like many of his Enlightenment contemporaries, Hume was particularly critical of the clergy. He argued that the character that must be maintained by members of this profession inclines to hypocrisy, since no one can maintain genuine religious sentiments for any sustained period. Also, it was in their self-interest to maintain the superstitious beliefs and practices of their own followers, as well as their opposition to rival sects. To avoid the public disorder caused by religious factions Hume favored the existence of an established church.

He criticized the natural or philosophical religion embraced by many of his enlightened eighteenth-century contemporaries. In his posthumously published *Dialogues Concerning Natural Religion*, he presented the most comprehensive critique of the intelligent design argument before Darwin. Hume argued that there is no reason before experience to think that order and apparent design must proceed from intelligence, and that it is only our parochial experience of human intelligence that suggests such a connection. Through the *persona* of his skeptic *Philo*, he argued that the analogy between the order found in nature, and the order and purpose found in the works of man is weak; that we experience order arising from other causes than intelligence; that our experience of the universe itself is limited in space and time and cannot form the basis for principles which operated at the beginning of the universe; and that intelligence in the only case that we experience it – namely in human beings – itself arises from natural causes. However, Hume rejected the possibility that there was chance or indeterminacy in nature, and was unable to put forward an empirically based alternative explanation for the order and design apparent in nature.

Hume also argued that the problem of evil was insoluble by any rational means. In his essay "Of a particular providence and a future state," he pointed out that one cannot legitimately infer more goodness in the creator than is actually found in the creation which is observable to us. While one can speculate about an afterlife that compensates for the injustices and

suffering of this life, one cannot establish it on any rational basis. Indeed, in his *Dialogues*, his skeptic *Philo* argues that the presence of natural and moral evil in this world should lead us to the conclusion that its creator, if powerful, is entirely indifferent to human conceptions of good and evil.

Conclusion

While he was still completing his *Treatise of Human Nature* in 1740, Hume wrote to Francis Hutcheson that in a cool moment he believed that his ideas would be more likely to furnish hints to the future rather than add to the sum total of human knowledge. This reflection was quite prescient. In 1776, the year of Hume's death, Jeremy Bentham, the founder of utilitarianism, wrote that the scales were lifted from his eyes when he read Book 3 of the *Treatise*, where he found "demonstrated, after a few exceptions made" that "the foundations of all *virtue* are laid in *utility*." Bentham added that the key difference between him and Hume was that while Hume used the idea of *utility* to account for the way things are, he (Bentham) used it to account for the way things *ought to be*. The most influential contemporary critic of his epistemology, Thomas Reid, wrote to Hume that he would always avow himself to be his "Disciple in Metaphysics." However, while Reid presented a naturalistic account of our cognitive faculties, he and other writers of the Scottish School of Common Sense rejected Hume's empiricism, his stress on the association of ideas in human thinking, and his skepticism. For them, unlike Hume, there is no conflict between our natural common sense beliefs and the foundations of scientific knowledge. While the most influential of his writings – his *History of England* – was the standard for its subject until well into the nineteenth century, Hume's rejection of the standard Whig account of development of the English constitution was vehemently opposed by republicans such as Thomas Jefferson. In general, while Hume's writings were seminal, his successors have challenged many of his arguments, and their central role has been to contribute to further empirical study of the many subjects he dealt with.

Abstract

The capacity to joke and perceive something as humorous is universal. However, what is held to be funny is relative. In most societies, there is a distinction between the diffuse humor of the common people and the institutionalized humor by experts at specific times and places. Humor ranges from mild joking to biting satire. Worldwide topics relate to the boundaries between nature and culture, self and other. Many jokes deal with commonly experienced ambiguities, dilemmas, and paradoxes. Functions of humor include entertainment, release of tension, cultural critique, and the marking of group boundaries. This article reviews some forms, domains, and functions of humor.

The Nature of Humor

The terms humor, joking, and laughter are often used interchangeably and are part of the semantic field of the comic that in turn belongs to the domain of expressive culture. There is no single acceptable definition of humor but scholars generally agree that it revolves around a sense of the incongruous or ludicrous. Humor is omnipresent yet elusive, nonsensical yet serious, friendly yet aggressive or hostile, universal yet specific. Humor and joking are part of the human condition yet may differ from time to time, place to place, and even from person to person. A joke can make sense across two millennia, as this 'stupid peasant' joke from ancient Greece testifies: "A peasant, having heard that parrots live for a 100 years, bought one to see if it was true." A joke may also change or lose its point as it moves between cultures. The 'dirty jokes' that provoke laughter in Tamil popular theater would hardly draw a smile from Dutch observers. Humor is notoriously hard to translate from one language to another.

A joke is something said or done in a playful manner to excite mirth. Jokes are relativizers, creating in a playful manner distance from turmoil and toil, misery and misfortune. Humor permeates all domains of public and private life. Worldwide topics include sex, food, health, death, the stranger, and lunatic. Understanding humor often requires intellectual effort, yet scholarly attention partly spoils the punch line. The comic is part of everyday life yet stands apart. Humor creates a momentary world of make-believe. It is closely related to laughter, yet one can appreciate a joke without laughing, and not all events and actions that trigger laughter are humorous.

The paradoxical nature of humor is further complicated by the fact that it is perception and performance, cognition and action, intellectual and emotional, institutionalized and spontaneous. Cognition is implied in grasping a double entendre or perceiving an incongruence. On the other hand, much humor touches the emotional stratum of cultural expectations and involves mimic, gestures, pantomime, and horseplay. An apt one-line summary of humor is "a play upon form" (Douglas, 1968) or "a play upon meanings" (Zijderveld, 1983).

The Study of Humor

The paradoxical nature of humor helps to explain why philosophers have been interested in it since ancient times as well as social scientists have long neglected it. Philosophers including Plato, who detested humor; Erasmus and Rabelais, who celebrated it; and Bergson and Plessner, who have devoted learned treatises to the mechanisms of joking and laughter. In their perspective, there is a bias toward intellectual and linguistic mechanisms, especially the awkward incongruity, perceived in surprise, which most thinkers define as the essence of humor.

Freud promoted the psychological study of joking and considered it a regression to infantile modes of thinking, an expression of anxiety, and a substitute for aggression and libido. Freud concentrated on *der Witz*, which is the quintessence of Yiddish humor: a short, pointed, witty story or pun. During the 1980s and 1990s, humor research has expanded both in terms of disciplines involved and number of publications. In 1988, the International Society for Humor Studies, an interdisciplinary professional association, launched the journal *Humor: International Journal of Humor Research*. Linguists and psychologists dominate the inquiry into humor but more recently it has become increasingly popular among scholars of cultural and communication studies, anthropologists, sociologists, political scientists, and clinical researchers (cf Nilsen, 1993). Over the past 15 years, publications have grown exponentially.

Anthropology

It is said that Bronislaw Kaspar Malinowski, one of the founding fathers of social anthropology, defined his discipline as the science of the sense of humor. Indeed, the anthropologist shares with the humorist a strategy – to use a Geertzian phrase – of making the familiar strange and the strange familiar. There are also family resemblances between anthropologists and tricksters (cf. Van Meijl, 2005). Both compensate physical weakness or lack of power with cunning and subversive humor. Common sense is disrupted, the unexpected evoked in order to enhance the awareness that reality is socially and culturally constituted. This relativist perspective may be essential for the cross-cultural study of humor, but the deep contextualization needed to understand humor gets in the way of anthropology's comparative perspective (Driessen, 1997).

Despite Malinowski's claim and anthropology's enormous archive of cultural variation, until the mid-1980s the vast majority of anthropologists neglected humor as a research

topic. So did sociologists (Zijderveld, 1983, 2011; Kuipers, 2006). Some early anthropologists studied humor from a folklorist and antiquarian perspective, but rarely as a resource for cultural analysis. In some fieldwork guides, humor is not even mentioned in spite of the fact that it is a finely calibrated barometer of the preoccupations shared by members of a society or group. Without understanding humor and laughter, one may never get to the core of a culture (Brandes, 1980). Radcliffe-Brown's article (1940) was a breakthrough, although his interest was in the structural implications and functions of joking relationships rather than their symbolic content. Mary Douglas found the essence of the joke in its attack on control. In the 1970s and early 1980s, anthropologists used semiotic and narrative approaches to study joking per se, not just its functions (Handelman and Kapferer, 1972). The first comprehensive, comparative anthropological study of humor and laughter appeared in the mid-1980s (Apte, 1985), and this event marked a considerable increase in case studies on humor in articles and books. Yet, humor remains for the most part a spin-off of other research topics, despite a growing awareness among anthropologists that it provides clues to what really matters in groups and societies. A good example is the intensification of political humor just before and throughout the so-called Arab Spring in 2011. The widespread use of humor in cartoons, comedy, graffiti, and raps expressed subversion and acted as a powerful vehicle for political activism. While the Arab world, in particular Egypt, has a long history of lampooning leaders, relatively new humorous genres such as rapping, stand-up comedy, and joking in blogs proliferated thanks to the new social media. Another striking example is the Italian comedian and agitator Beppe Grillo. This political buffoon has become a serious political force with his protest movement 'Five Stars.' It caused a landslide in the municipal elections of early 2012.

Anthropologists and comics share a relativist perspective. It is no surprise that the anthropological essay (Miner, 1956) and the ethnographic documentary have been parodied both within and without anthropology. A recent example on YouTube is 'Fest des Huhnes' (Festival of the Chicken) in which an African anthropologist documents the 'strange' customs of a mountain 'tribe' in Austria. Horace Miner's famous essay on body ritual among the Nacirema is a classic in teaching anthropology. Grant McCall's (1971) parody of British society and structural analysis is another example. In a brief article, taking 'Decimal Day' when the United Kingdom decimalized its currency as a starting point, McCall uses Lévi-Strauss, Dumont, and Srinivas in his burlesque of the British estate system, beverages, and other 'primitive classifications based on the four-part scheme.' A widely known case of self-mockery is the bestseller *The Innocent Anthropologist* by museum anthropologist Nigel Barley (1983).

The Many Faces of Humor

Genres

In most societies and cultures, there is a distinction between the diffuse joking of people as part of daily sociability and the institutionalized joking by virtuosi at specific times and places, such as the clown in wedding ceremonies in Polynesia, the television comedian on New Year's Eve, the trickster in a Javanese *wayang* play, or the regular stand-up comedy acts in New York, Amsterdam, or Sydney cafés. Jokes and pranks may provide the main fabric of which men are bound to each other on a daily basis as in Andalusian agrotowns (Brandes, 1980; Driessen, 1983).

Humor ranges from mild jokes to biting satire. A first type is benign humor that is simple, informal, and harmless, intended for diversion and repose. It does not unsettle the course of daily life. In metropolitan Egypt, for instance, during the regimes of Nasser, Sadat, and Mubarak, joking was the lubricant of social life. Persons who lacked a sense of humor 'had thick blood' and were scorned. A second type of joking is wit, banter, persiflage, or punning. This is a game of language and intellect, using irony to tackle discrepancies between appearance and reality. A third type is black or gallows humor, which challenges and mocks tragedy and misery, for instance, the 'Darwin Awards' on the Internet. A fourth form is satire, militant, aggressive, or hateful joking, meant to criticize authority, common sense, and conventions, as in Carnival around the world. The trickster of the Winnebagoo, Pueblo, and other Native Americans is a quintessential satirist, as were the Eurasian court jokers. The political cartoonist is a modern example of a satirist (Jansen, 2009) as is the stand-up comedian in metropolitan society. Finally, obscene and sick humor are categories found in many different societies. A recent example from the Netherlands in 2012 are so-called April Fool's jokes in which a suspicious parcel was placed at a synagogue in a rural town and a 'sea mine' dropped into a city canal. After massive interventions by the fire brigade and security forces it turned out that both objects were fake and part of a First of April 'joke.'

Domains of Joking

Worldwide, topics of humor deal with the boundaries between nature and culture, in particular with sex, food, health, and death as well as with social boundaries (us and them, strangers and lunatics). It has often been noted that it is hard to translate a joke from one language to another, especially in the case of puns and witticisms. Language is both a topic and vehicle of humor. Linguistic play and rhetorical devices, such as incongruity, paradox, and irony, are central to puns, tall tales, and riddles. Anthropologist Napoleon Chagnon, struggling to learn Yanomamö, was the victim of verbal humor. Informants made a sport of inventing obscene and ridiculous names for people such as 'dirty rectum' or 'feces of the harpy eagle' which Chagnon wrote down and used without knowing their meaning (Driessen, 1997). Apaches stage joking imitations of the 'whiteman' with exaggerated, loud, and fast speaking (Basso, 1979). In many societies, for instance, the Inuit, verbal virtuosity is expressed in duels in which humorous and obscene insults are recited to ridicule opponents. In Egypt, these verbal mock fights are ritualized in male coffee houses, for instance, "Your father puts on his underpants with a shoehorn"; "when your father sees a garbage truck coming, he lies down like a heap."

There is also a strong interdependence between gender and joking (Herzog, 1999; Crawford, 2003). Sexuality is a core subject of joking everywhere and humor is an important

element in attraction among the sexes. In most societies, there is gender inequality in joking. While men tend to use more aggressive humor and laugh louder in public spaces, women tend to remain more passive and restrained. Men play more prominent roles in ritual public humor. There are exceptions. Older women may publicly engage in humor and even compete with men. In Pacific island communities, female clowns play important ceremonial roles (Hereniko, 1995). In many Mediterranean societies, women perform for women mock imitations of men, their sexuality included. In Western society, professional female comedians are recently gaining prominence, an obvious indication of female emancipation.

Age is important in joking. Psychologists have noted the crucial role of humor in personality development and language learning. It serves as a general educational device. Children and adolescents have a special sense of humor with which they mock adults. Adults often find amusement in encouraging children to imitate adult etiquette. There are striking gender differences in the nature, devices, and approval of children's jocular behavior.

A widespread kin-related form of institutionalized humor is the joking relationship. Some categories of kin are licensed, sometimes even obliged, to tease, ridicule, and insult persons and groups belonging to another category, who must accept it without taking offense. In many societies, kin of the opposite sex who are potential sexual partners are involved in joking relationships. In Western society, mild joking is allowed with grandparents. Outside the kinship domain, reciprocal joking relations may occur, for instance, on the work floor or in hospitals and nursing homes. Over the past few years, the author observed many cases of reciprocal joking between nurses and elderly clients in a Dutch rest home. One particular nurse was walking the thin line between joking and humiliation when she asked a lady of 87 who regularly received brief social visits by a male neighbor of 79 whether she had thought of putting a condom on her bedside table.

Where governments fear freedom of expression and rigidly demand conformity, political humor is repressed yet flourishes, as is the case in most dictatorships. 'Joking up' is a weapon of the subordinated, whereas 'joking down' may act as a means of the powerful to express their superiority. Among near-equals, humor may play a role in what Freud called the narcissism of minor differences.

One of the main domains of joking in the globalizing world is ethnicity. Ethnic jokes make fun of supposed and farcically exaggerated effects in certain ethnic groups and nations. The deficiencies appear in pairs, e.g., the stupid and canny, the stupid and cowardly, and militarism and cowardice. Such dualities relate to commonly experienced ambiguous and contradictory situations (Davies, 1990). The telling of jokes may be, but not necessarily, an expression of racism and discrimination. Ethnic and many other jokes have a complex relationship with everyday experience.

Religion is replete with ironies and paradoxes. Consequently, joking, laughing Gods, and holy fools are to be found in the beliefs and rituals of many religions, local and global. There are counter-virtuosi who disturb and suspend the rigid ritual order by burlesque, inversion of roles, and sexual and scatological humor. Berger (1997) even argued for a 'theology of the comic' in which the experience of the comic is a promise of redemption.

Joking is not only a feature of face-to-face communication but also a major element in newspapers and magazines, movies, radio, television, and the Internet. Comic books have become a popular art form. There is musical humor and humor in novels and poetry, increasingly taken seriously by scholars of the humanities. Humor is also an effective device in advertising. In sum, humor permeates all domains of (semi-) public and (semi-) private life.

Functions and Meanings

Given the Protean nature of humor and its widely diverse manifestations, it is not surprising that there is no universal structure of meaning to humor. Its content largely relates to commonly experienced ambiguities, dilemmas, and paradoxes that are part of the human condition. Humor is one of the ways to deal with such experiences, and this is the universal meaning of humor. Much humor involves entertainment. It produces pleasure and smoothes social interaction. One of the most widespread popular psychological and functionalist theories has it that humor plays an important role in conflict resolution by releasing tension. Related theories hold that it is a tool of cultural critique and social control by highlighting taboos and key values. Another social function of humor and joking is that they mark group boundaries and help to promote a sense of belonging both in face-to-face and digital communities, sometimes by testing and challenging social cohesion. Humor and its different genres can also effect greater commitment, regulate embarrassing behavior, and sustain serious interaction. And they are relativizers, creating in a playful manner distance from turmoil, misfortune, and misery.

All these functions are present in the humor and laughter of young marginalized men in a city of Northern Morocco (Juntunen, 2002). In this context, humor and laughter serve as a relief-providing vehicle for young men with limited access to economic and political resources. Besides providing relief, joking among these young men also has the function of identity and solidarity building. The following joke popular among these men shows how the backwardness of the peasant turns into passive resistance. A man from the Ministry of Agriculture went on a tour of inspection in the countryside. He came across a peasant with a flock of sheep and asked him: Where do the sheep get their water? The black ones or the white ones? The black ones. There is a well over there. And the white ones then? The white ones as well. And where do they graze? The black ones or the white ones? The black ones. Up over there. And the white ones? The white ones as well. And how much do they pay for the wool here? Of the black ones or the white ones? The black ones. Twenty dirhams a kilo. And the white ones? The white ones as well. The civil servant has been writing everything in his official file but now had started to lose his temper. He asked sharply: Why do you keep on asking 'the black ones or white ones?' Because the black ones are mine. And the white ones? The white ones as well.

Trends in humor research show an increased interest in the healing power of humor and laughter in cross-cultural communication, psychotherapy (laughing sessions), and

clinical research. Cliniclowns in child hospitals seem to have relaxing and comforting effects on seriously ill children. Ethnic humor is a topic of growing relevance as are differences in joking styles and tastes. Recent issues of the journal *Humor* include articles on the fear of being laughed at, Chinese humor, and humor in poetry and politics.

Abstract

This article summarizes our current understanding of the theoretical bases of eating behavior, and the associated neural structures and signal molecules. In particular, the interaction between brain stem and forebrain regions subserving energy regulation is outlined, as well as the essential integration of these systems with those involved in rewarding aspects of food intake.

Energy transfer is the essential foundation of life. All biological processes require energy to proceed, and they do so by a series of biochemical reactions or transformations. Animals continually lose energy in the form of heat loss to the environment and to produce muscular activity for the heart, diaphragm, and skeletal motion. To fuel these processes requires that we have a continuous supply of suitable energy. That supply is food, which we, both, store and use as biological energy. This energy is most commonly expressed in terms of kilocalories (kcal) or kilojoules (kJ), although the kilo prefix is sometimes omitted.

History, Homeostasis, and Allostasis

Early theorists realized that survival is a question of making energy consumed equal to energy expended. Homeostasis is a concept, advanced by Walter Cannon (1929), which is consistent with this premise. Basically, it expanded on an earlier concept by Claude Bernard that relative constancy of the internal milieu – in this case energy content or flow – was essential for life. Cannon argued that dedicated physiological regulatory mechanisms were responsible and necessary for homeostasis.

Dual Center Theory

Recognizing that energy input via eating was essential, Eliot Stellar (1954) proposed a dual center model for feeding in which one region of the brain (the ventromedial hypothalamus) was considered a satiety center and an adjacent region (the lateral hypothalamus), a hunger center. These two regions each receive neural and hormonal inputs relevant to a variety of aspects of food, but ultimately the balance of neural activity between these two structures was thought to determine whether eating would occur (for example, due to hunger) or would not occur (for example, due to satiety). Today, some 60 years later, our knowledge of the brain structures, cells, and genes involved has proliferated greatly, yet the theoretical underpinning of much research is still fundamentally based on these opposing or reciprocal concepts of excitation of feeding (hunger) and inhibition of feeding (satiety). Another type of proliferation has taken place during these 60 years – our national waistlines as an obesity epidemic – because at a population and individual-level food intake has systematically exceeded expenditures. There is nothing constant about that fact, so the original concepts of balance or homeostasis are either inadequate or incomplete.

Allostasis

One of the problems with the simplest models of homeostasis is that they are reactive: when something drifts out of range, it is corrected. Yet many examples suggested that organisms were able to predict events, and several embellishments were made to the basic model. Most recently, the concept of allostasis has been promoted (Sterling, 2012). To simplify greatly, the concept of allostasis means that organisms do not regulate for constancy, but rather change the levels of regulation depending upon the prevailing environmental conditions. Another problem with classical homeostasis is that it requires some internal representation of the ideal: a set point, and it has proven difficult to demonstrate such an entity. In contrast, allostasis does not require a set point, simply an adaptive system with multiple inputs hard wired in such a way that the net output will be predictable for a given set of inputs. Applied to body weight which, as will be discussed is the output of multiple systems, allostasis is closely related to the idea of settling point (Wirtshafter and Davis, 1977).

Environmental Influences on Eating

Perhaps the conscious sensations that most affect our eating behavior are the chemical senses of smell and taste, and their synthesis as flavor. In an evolutionary context, these senses were important to locate food and evaluate its safety. Today, finding safe food in a modern society is not usually a problem: indeed, our brain is poorly prepared for the cornucopia of alimentary sensation with which it is bombarded. I will mention four aspects of taste/flavor that affect consumption: quality, intensity, variety, and economics.

Taste Quality

Foods or fluids that are sweet, via a family of so-called sweet receptors on the tongue and palate, are most readily accepted and ingested. Substances that are bitter generally are rejected. Fat-containing foods are also highly palatable, perhaps because

of their texture although recent work suggests there may also be fatty acid receptors on the tongue. Substances that combine sweet and fat are almost irresistible, like many desserts! Salty tastes also enhance the palatability of some commodities.

Taste Intensity

Intensity is related to the relative concentration of the tastant molecules in a sample, and their access to the relevant sensory receptors. Many elementary tastants show a preference-aversion function. When the concentration is very low, the taste is not or barely detectable (bland) and intake is low. As concentration increases, intake also increases up to a maximum beyond which it falls again – very high concentrations become less palatable. Sugar has a particularly long and pronounced preference side to this function.

Food Variety

Not only do real foods contain more than one tastant or odorant, we generally eat several different foods in a short time, or at least have a choice. The phenomenon of sensory-specific satiety (more accurately, satiation, see later) demonstrates that when people are given a succession of choices of flavors of even the same food (for example, yogurt) the amount consumed is considerably more than when only one flavor is presented. In its simplest form, this resembles habituation (to a given flavor) and dishabituation to the new flavor. The phenomenon of alliesthesia is related – the perceived palatability of a commodity declines as more of it is consumed.

Economics

Ecological foraging theories emphasize that the energetic effort expended to obtain food cannot, in the long term, exceed the energy yield from that food. In modern societies, effort is most usually in the form of time and monetary exchange. In particular, food that is immediately available at modest cost promotes 'opportunistic' eating – for example, vending machines or fast food (Rowland, 2012). Consumer economics describes the relationship between consumption and cost as a demand curve: not surprisingly, demand declines as price increases with the caveats that not all commodities show the same shape of demand curve and that price embodies aspects of time and money, as well as perceived social benefits. This cost–benefit aspect of the environment impacts the allostatic mechanism(s) mentioned previously.

Hunger, Satiation, and Satiety

Hunger

Hunger is the unpleasant sensation that motivates us to seek out and consume food. Homeostatic theories emphasized that hunger should be derived from internal deficiencies, such as an empty stomach of low availability of circulating metabolic fuels to critical sensors, presumably in the brain. However, hunger is not unconditionally correlated with such internal signals and people report hunger even when they are well-nourished. A concept of opportunistic feeding emphasizes the key role that the mere presence or prospect of food has on consumption. Our distant ancestors lived under continuous food insecurity – they did not know when the next meal would arrive and so the best survival strategy was to eat when food is available. Today, it may be that lower income individuals have the same perceived food insecurity and that may contribute to their overeating and relatively higher incidence of obesity. That does not deny the fact that a period of either acute or chronic lack of food (deprivation) will not increase hunger ratings and the motivation to seek food – they do – but deprivation is not the only trigger of hunger. Ghrelin is a hormone released from cells in the stomach when food is not present, and is thought to contribute to the sensation of hunger related to deprivation (Mason et al., 2014).

Satiation and Satiety

Satiation and satiety refer, respectively, to the early and late phases when hunger is absent after eating. Thus, satiation refers to processes that terminate an ongoing feeding episode while satiety refers to processes that suppress hunger for a more extended period of time. Once food has passed the oral cavity and reached the stomach, it initiates a temporally overlapping cascade of events that contribute to satiation and satiety. Food has bulk, and gastric distention is one such factor. The chemicals in the food, either before or after breakdown by digestive enzymes, stimulate specific receptors on enteroendocrine cells lining the gastrointestinal tract that lead among other things to release of hormones that either enter the blood stream and/or act in a paracrine fashion to stimulate local sensory nerve endings (Mayer, 2011). Either way, via neural and vascular pathways, these signals reach the brain. Some of these signals emanating from the upper parts of the tract, such as cholecystokinin, start signaling while eating is still going on and are candidate satiation hormones. Others, such as peptide YY are released from cells further down the intestine and so are not stimulated until food had been partly digested and propelled to that location by peristalsis, and are instead candidate satiety hormones. These neural and hormonal signals are thought to impinge on a common region of the hindbrain, the nucleus of the tractus solitarius (NTS) and/or the adjacent area postrema (Grill, 2010).

Neurobiology of Hunger and Satiety

Several key neural systems have been identified that participate, at a minimum, in the ebb and flow of hunger and satiety (Berthoud, 2011; Grill and Hayes, 2012). The most studied are systems that derive from cell bodies in the arcuate nucleus, which is situated medially at the base of the hypothalamus. Within the arcuate nucleus, there are two principal phenotypes of neurons. One type coexpresses genes for neuropeptide Y (NPY) and agouti-related peptide (AgRP). Administration of either NPY or AgRP into the brain of rodents causes them to hoard and eat food, and so these neurons are believed to be endogenously activated during states of hunger. A second type expresses the proopiomelanocortin (POMC) gene and, of several products from this gene transcript, the most relevant is α-melanocyte stimulating hormone (MSH). Administration of

α-MSH into the brain of rodents causes them to eat less, and so these neurons are believed to be normally activated during states of satiation or satiety. Alpha-MSH exerts its anorectic action primarily via type 3 and/or 4 melanocortin (MC3, MC4) receptors found in high abundance in the paraventricular nucleus (PVN) of the hypothalamus. Additionally, AgRP acts as an antagonist or blocker at MC4 receptors, so assuring a reciprocal action between these neuronal types. Further, both of these classes of neurons have receptors for blood-borne insulin and leptin, and so are influenced by these circulating hormones related to energy status. Recent evidence suggests that there are several functional subtypes within these two classes of neurons, including different parts of the brain to which they project. Thus, the 'hypothalamocentric' theories of food intake focus around the excitatory and inhibitory controls of these neurons, and whether they could eventually be manipulated for therapeutic purposes.

An additional consideration is the role of the hindbrain and in particular NTS. This is essentially the only region of the brain beside the PVN that expresses high levels of MC4 receptors, suggesting a prominent role for α-MSH in this region of the brain as well. There are bidirectional axonal connections between the NTS and the hypothalamus (and other forebrain regions) suggesting that descending projections from the hypothalamus can modulate the excitability of primary afferent information (taste, enteroendocrine) information ascending from the NTS to the rostral brain (Grill and Hayes, 2012).

Reward Systems

The systems described in the previous section are well-suited to homeostatic-like control of food intake, by controlling and modulating the flow of primary sensory information including endogenously secreted molecules. However, this does not address the issue of how or why taste and availability factors so profoundly influence total food intake and eventually body weight in an allostasis-like manner. Food is well known to act as a primary reinforcer of behavior, and a common reward system may be responsible for reinforcing a number of classes of behavior. This common substrate is a small population of neurons in the ventral tegmental area of the midbrain that express the transmitter dopamine and send axonal projections to the ventral striatum or nucleus accumbens and the frontal cortex. These neurons are potently activated by food and by cues related to the anticipation of food. There is some evidence that, rather than signal reward per se, these neurons encode differences between expected reward and that received (a prediction error). Additional signal molecules related to reward are endogenous opioids and endocannabinoids, both of which are known to affect food intake. Thus, activity within the reward system is thought to affect food intake, to some extent independent of the homeostasis-like systems described previously, although the systems must interact (Berthoud, 2011).

Abstract

Hunter-gatherer archaeology is the archaeological field of study that deals with hunter-gatherers, which are societies that procure most of their food from hunting, gathering, and fishing. Humans have been hunter-gatherers for most of their existence. Until the first food-producing societies developed, hunter-gatherers lived almost everywhere and this subsistence regime constituted the only way of living that humans had. So temporally, hunter-gatherer archaeology extends from the very first hunters documented in the prehistoric past until today. This article reviews the main characteristics of hunter-gatherer archaeology, the history of research, and current developments.

Introduction

At the heart of many anthropological theoretical frameworks is the assumption that we as humans are fundamentally hunter-gatherers. By the 1950s, paleoanthropologist Raymond Dart considered that hunting and a lust for meat "… drew the man-apes out of the forest and was a main force in human evolution" (Sussman, 1998: 121). Dart defined the basis of what was called the "hunting hypothesis" (Cartmill, 1997: 511), and later the writer Robert Adrey (1976) popularized it. Although the hunting hypothesis has since been disproved, when it was established that our hominin ancestors were mostly scavengers (Binford, 1981; Shipman, 1983), this view of the pivotal role of hunting and gathering lifeways in human evolution has had considerable traction in popular literature (e.g., Stewart, 1969). The hunter hypothesis is still evident in social scientific thought as well. For instance, a textbook on Evolutionary Psychology proposes that "… the mind is a set of information-processing machines that were designed by natural selection to solve adaptive problems faced by our hunter-gatherer ancestors" (Cosmides and Tooby, 1997: 1). Therefore, since the role of hunting and gathering in our history and our present continues to be debated, it should come as no surprise that hunter-gatherers have been a highly visible subject in anthropology and archaeology since the 1960s.

Hunter-Gatherer Archaeology

Hunter-gatherer archaeology is the archaeological field of study that deals with hunter-gatherers or foragers (often used interchangeably, i.e., Kelly, 1995: xiv, although not without controversy). Hunter-gatherers are "those who do or did procure most or all of their food from hunting, gathering and fishing" (Kelly, 1995: 3). But, as always in human matters, nothing is that simple. Kelly himself states that hunter-gatherers "do grow some of their own food, trade with agriculturalist for produce or participate in cash economies" (Kelly, 1995: 3).

Humans have been hunter-gatherers for most of their existence. Up to 12 000 years ago, when the first food-producing societies developed (Lee and Daly, 1999), hunter-gatherers inhabited nearly all environments globally and constituted the only lifeway available to humans. Thus, spatially hunter-gatherers are "archaeologically documented in environments ranging from tropical rain forests to the Arctic – and nearly everywhere archaeologists have looked in between" (Johnson, 2014: 18). Temporally, hunter-gatherer archaeology could be extended to the present day because foragers still persist in certain parts of the world. Even in the modern cities, the homeless could be considered as foragers acting in an urban environment (from an activist perspective, see Zimmerman et al., 2010). As Zimmerman et al. (2010: 444) observe, "There can be archaeology of ten minutes ago as easily as there can be archaeology of 10 000 years ago," which is a valid statement for hunter-gatherer archaeology more generally.

Main Characteristics

The archaeology of hunter-gatherers is often very different from the kind of archaeology seen in the media. Far away from castles, marble monuments, and splendorous graves, included in the field of classical or urban archaeology, it can frequently be very basic and straightforward.

The main features of hunter-gatherer archaeology are:

1. An interest in the recovery of any minute item related to human behavior: Because hunter-gatherers are mostly nomadic (although sedentary lifestyle is recorded in some hunters-gatherers, mostly exploiting aquatic resources, as in the Northwest Coast of North America, see Ames, 1985), they have fewer material possessions than, for instance, sedentary agriculturists. Their objects are more transportable, namely, more compact, smaller, and less fragile than the possessions of sedentary people. Also, in contrast to the villages and cities of sedentary groups, hunter-gatherers have sparser population distributions and correlatively they create more archaeological sites although with lower artifact densities. Finally, one must consider the durability of the materials used by hunter-gatherers. Many materials used by hunter-gatherers were perishable and their preservation depends on the particular conditions of deposition

or their antiquity, with the noteworthy exception of lithic materials (see below). In this sense, hunter-gatherer archaeologists are focused even in the smallest details in their research, in a context of relatively artifact scarcity (when compared to a village or urban site).

2. A strong focus on technological issues, especially those related with lithic materials: The poor preservation of many materials and the excellent preservation of stone is the reason that much hunter-gatherer research deals mainly with lithic technology. When dealing with the archaeology of the earliest humans or human ancestors, usually only lithic artifacts are recovered. In more recent times, new technologies emerged and more materials survive to be recovered by archaeologists (as worked bone, ceramics, metals, etc.). However, all hominins and humans must have used other materials that simply were not preserved. This fact poses a major challenge to hunter-gatherer archaeology since, as the motto goes, the absence of evidence it is not evidence of the absence. For instance, the lack of wooden artifacts does not mean that wood was not exploited: It could simply not have been preserved. Therefore, although stone tools are used in other contexts, such as urban sites, lithic materials are the bulk of what archaeologists analyze in hunter-gatherer sites.
3. An interest in human mobility patterns and circulation: The fact that hunter-gatherers are mostly nomadic or mobile has naturally led to considerable research in this area (see below).
4. An emphasis on understanding subsistence patterns: Many of the archaeological remains found at hunter-gatherer sites were associated with food procurement.
5. Less interest in the symbolic aspects and belief systems arguably due to problems of interpretation, given the lack of context or continuity to interpret symbols present in rock art or decorated artifacts. But also, as the theoretical framework mainly used in hunter-gatherer has been processualism (see below), this lack of interest in symbolic issues was linked to a preference for materialist perspectives (see Archaeology, Theory in). However, although less often employed than in other areas of archaeological focus, interpretive theoretical frameworks have recently developed in hunter-gatherer studies (see below).

Anthropology, Archaeology, and Hunter-Gatherers

As Bettinger (1987: 121) has noted "there is little that separates archaeologist from cultural anthropologist where hunter-gatherers are concerned and many scholars move back and forth between the study of living and extinct hunter-gatherers without perceptible difficulty." This is because archaeologists have utilized ethnographic information to develop analogies (i.e., Cummings, 2013) or provide a frame of reference (Binford, 2001) for research in different times and from many theoretical standpoints (see below). Hunter-gatherer studies are today at the main intersection between anthropology and archaeology. In that intersection, anthropology contributes the theoretical standpoint and the linking between living context and archaeological context whereas archaeology has contributed 'deep' time and a variety of behaviors that anthropology cannot record. But, hunter-gatherer anthropological knowledge was created in a colonial or postcolonial context (Cummings, 2013) whereas hunter-gatherer archaeology has mostly focused in hunter-gatherers before they occupied marginalized geographical and social spaces. Archaeology is thus the only discipline that allows for the study of hunter-gatherers before colonialism. One of the great strengths of archaeology is its ability to provide examples of human behavior that are not recorded in the present or the historical record, but that nonetheless characterized the human experience at some point in our species' history. The present therefore can be useful in studying the past (as it is in Middle Range Theory, for instance; see below), but it should not limit our interpretations of past hunter-gatherer societies.

Bettinger identifies two perspectives on hunter-gatherers studies in the early and mid-twentieth century. The first characterized hunter-gatherers as primitives and remnants of the Stone Age (i.e., Murdock, 1934 and its suggestive title) which "emphasized the things (hunter-gatherers) lacked that more advanced cultures would later have" (Bettinger, 1987: 122). This model endured until the advent of the second in 1966, when the "Man the Hunter" conference was held in Chicago. Organized by Lee and DeVore (1968), this symposium brought together researchers from all over the world to develop a new model of hunter-gatherer societies. Dubbed the "generalized foraging model" (Isaac, 1990), this new model relied heavily on anthropological theories derived from the New Ecology and Neofunctionalism (Bettinger, 1987).

The generalized foraging model considered five characteristics: (1) egalitarianism, (2) low population density, (3) lack of territoriality, (4) a minimum of food storage, and (5) band as a preferred form of social organization (Kelly, 1995). As Kelly (1995) has pointed out, the most critical part of this model was Marshall Sahlins' (1968) formulation of the "original affluent society," which generated a picture of hunter-gatherers as "spending relatively little time working, (having) all the food they needed and (spending) leisure hours sleeping or socializing" (Kelly, 1995: 16). Thus, from this perspective agriculture was not a breakthrough but rather "a lifeway adopted only under dire circumstances" (Kelly, 1995: 18). As an answer to *Man the Hunter*, the volume *Women the Gatherer* (Dahlberg, 1981) challenged the gender bias implied by both the title and content of the former by stressing the role of women in hunter-gatherer societies and their importance as providing critical resources to the diet. Although this book was important in terms of establish gender bias operating in hunter-gatherer studies, it suffered from the same fault that *Man the Hunter*: hid hunter-gatherer variability (Wobst, 2011) in order to emphasize similarities (Kent, 1996).

The movement to critique this homogenizing perspective of hunter-gatherers began almost simultaneously with the work of Wilmsen (1989) and Headland and Reid (1989) in different parts of the world. They suggested a different view, that of hunter-gatherers as dependent on trade with food-producing neighbors as well as their own part-time cultivation or pastoralism. This 'revisionist critique' has also generated reactions (see Shott, 1992 for a review) but slowly it began to gain adherents leading to a wide diversification in hunter-gatherer studies.

An Archaeological Perspective: Hunter-Gatherers and Processualism

In the 1960s neofunctionalism took the lead in anthropology. Neofunctionalism was derived from Systems Theory, and its core concepts were incorporated into the emergent New Archaeology or Processualism (see Archaeology, Theory in). Starting as a critique of the so-called normative theory (which asserted that artifacts reflected cultural norms), which was advocated by archaeologists and anthropologists employing a culture history theoretical perspective, Processual Archaeologists advocated for a scientific archaeology following the Hempelian deductive-nomological model of explanation and the Hempelian hypothesis formation/testing model (O'Brien et al., 2005: 110). Processualism also criticized culture history's focus on homogeneity and instead began to consider variability within ancient societies. With the advent of Processualism, the scene was set for a new perspective on hunters-gatherers. In fact, most of the research by one of the main advocates of Processualism, Lewis Binford, was devoted to hunter-gatherers.

As Binford stated, processualist archaeologists needed to construct Middle Range Theory as a mean by which the static archaeological context was connected with the dynamic and systemic context (behavior) that created it. In order to construct Middle-Range theories, Processualism explored actualistic studies (including experimental archaeology, ethnoarchaeology, and taphonomy). Among them, ethnoarchaeology gave a new impulse to the archaeological study of modern hunter-gatherers (see Ethnoarchaeology). A good example of an archaeological processualist perspective on hunter-gatherers is the Forager-Collector continuum model posited by Lewis Binford (1978, 1980). Departing from his own ethnoarchaeological work, Binford identified two extremes on a spectrum of mobility patterns among hunter-gatherers: from foragers on one end to collectors on the other. Binford attributed residential mobility, or movement of an entire group from one camp to another, to the former and logistic mobility, or movement of a small group from a residential base camp to a place to perform a specific task, to the latter, with a continuum of possibilities in between. Binford argued that the kind of mobility was dependent on the kind of environment under study: Where access to resources is temporally or spatially limited, a variety of measures will be taken to extend the utility of those resources (Bettinger, 1987). In environments that are spatially and temporally homogeneous (without seasons of shortage), there is no need to store food in anticipation of future scarcity. Under these conditions, hunter-gatherers exploit the resources near their residential base and then move to an unexploited area. Thus, foragers move consumers to food resources and map onto resources (Bettinger, 1987). In environments where resources are spatially and temporally heterogeneous (with periods of shortage), incongruities between distribution of population and resources require some form of compensation. Minimally, hunter-gatherers have to implement storage (a practice associated with resources obtained in bulk over a short period). Thus collectors move residentially to key locations that are not necessarily related to food supply, and then use logistical travels by small groups to bring resources to the residential base. "The forager responds to temporal and spatial resource shortage by residential movement; the collector responds to temporal shortage by storage and to spatial mismatches between population and resources by logistical mobilization" (Bettinger, 1991: 70). After its proposal, this model was tested in many archaeological cases around the world and found to be an accurate predictor of hunter-gatherer mobility.

Alternative models signaled differences among hunter-gatherers in different terms. For instance, Woodburn (1980, 1982) proposed a distinction between delayed and immediate return hunter-gatherers where delayed return groups focused on long-term storage, which eventually leads to inequality, and immediate return groups focused on producing food for rapid consumption. Bettinger and Baumhoff (1982) developed a traveler-processor model which posited a continuum of hunter-gatherer strategies by specifying relationships between population and resources and settlement and subsistence patterns. They posited that as population increased from low (traveler situation) to high densities (the processor situation), diet breadth and processing cost would increase.

Finally, Processualism and later Evolutionary Ecology or Behavioral Ecology (Winterhalder and Smith, 2000; Kelly, 1995) favored optimal foraging models starting in the 1980s. Initially taken from biology, these studies provided "a yardstick of objective economic rationality as a basis for the comparative study of human behavior" without which "it would be impossible to know whether human behavior was governed by cultural norms and ideas or by rational, self-interested individuals" (Bettinger, 1987: 135). In anthropology, optimal foraging theory assumes that human decisions are made to maximize net rate of energy gain. Some of the models deal with mobility although others include different ways to evaluate energy cost and gains. In the case of diet or diet breadth models, optimal foraging theory is employed to evaluate how many different species hunter-gatherers should exploit while patch choice models examine how hunter-gatherers will select an environmental patch to exploit.

Hunter-Gatherer Archaeology Today

In his review paper in the late twentieth century, Shott (1992: 864) argued for a synthesis of the general and the particular, one that would combine "a legitimate concern for case-specific historical developments with a commitment to general theory and explication" and asserted that archaeology would have an important role to play in forging this synthesis. As Shott expected, the 1990s was indeed a stimulating decade in hunter-gatherer studies. New research capacities provided by computers and the Internet allowed for the elaboration of a series of 'global' studies on modern hunter-gatherers aimed at elucidating general patterns (Cashdan, 2001; Henrich et al., 2006; Hill et al., 2011 among others).

Processualist archaeologists also have been elaborating studies at a global scale (Binford, 2001; Johnson, 2014; Kelly, 1995; Marlowe, 2005). For instance, using a Behavioral Ecology perspective, Kelly (1995) reviewed a series of hunter-gatherer groups focusing in subsistence, mobility, exchange, group size, and other characteristics to analyze hunter-gatherer

variability. Kelly's has been a preferred textbook in many archaeological courses around the world and it was highly influential. Nevertheless his database pales in comparison to Binford's (2001), in which by using environmental and ethnographical data he constructs generalizations and propositions "developed from ethnographic patterning among hunter-gatherers as a tool for archaeological research" (Johnson, 2014: 7).

From Binford's and Kelly's works, certain general patterns on modern hunter-gatherers were established. For instance, that hunter-gatherers' dependence on plants for subsistence decreases as latitude increases (at low latitudes hunter-gatherers are often primarily dependent on plant foods whereas at high latitudes, low population density hunter-gatherers are primarily dependent on animal foods) and that variation in subsistence is conditioned by effective temperature (a measure of growing season), population density, and availability of aquatic resources (Binford, 2001), allowing higher population densities along productive coasts and large rivers (Binford, 2001; Kelly, 1995). Also it was proposed that foraging groups in productive environments travel shorter distances and have smaller home ranges and higher population densities than societies in less productive environments (Kelly, 1995; Binford, 2001) as long as groups that rely more on hunting tend to have lower population densities, occupy larger areas, and move more frequently over greater distances (Kelly, 1995).

Postprocessualist archaeologists also have dealt with hunter-gatherers. As an example of this theoretical framework, Classen's (2012) work on Eastern US caves is noteworthy. Claasen draws on a body of evidence of 'cave rituals and ritual caves' established for Mesoamerica to elaborate a list of expectations about characteristics of ritual caves and offerings for hunter-gatherer groups. Her list for defining sacred caves includes: presence of flowing water, items of personal adornment left as offerings, items frequently burned, and/or broken, among others. Claasen then looked for these characteristics in a series of Eastern US caves occupied during the Archaic period. She reviewed the characteristics of nonhuman bone, mollusks, hematite, rock features, and stone tools recorded in those caves to finally conclude that they were utilized for ritual activities. She actually proposes that "Caves are so important in historic accounts of origins and homes of deities and culture heroes that rather than defaulting to camping to explain the material culture found in caves, the default explanation should become ritual" (Classen, 2012: 259–260). In terms of frameworks, today, most hunter-gatherer archaeologists are engaging a personal theoretical mix which includes Processualist and Postprocessualist approaches. The paradigmatic case in anthropology should be Tim Ingold's works (discussed below).

Biases

While promising, this state of the art still presents certain biases. One of the most pervasive is that most studies of modern hunter-gatherers are devised to model our ancestor's behavior (i.e., Marlowe, 2005; Ströhle et al., 2010; King, 2013). In addition, a great deal of hunter-gatherer archaeology is directed to early hominins or the 'peopling' of certain regions. In the Americas, this is manifest in the large body of work focusing on the Pleistocene–Holocene transition. Late Holocene hunter-gatherers, those who lived after the Ice Age, receive far less attention in international publishing despite an abundance of examples and the good preservation of sites from these times. For instance, and just as an example, on examination of all issues of the journal *Before Farming* (from the first issue in 2003 to the last in 2012), which specializes in hunter-gatherers, almost 30% of the papers published pertained to Paleolithic Europe and the Levant, followed by modern and prehistoric South Africa (15%), and modern and prehistoric Australia (11%). There are also spatial biases: The case of South American hunter-gatherers is illuminating. Kelly's (1995) database contains only 8 South Americans groups (5 of them from Amazonia) versus 50 North American groups (Kelly, 1995; Figure 1.1, 4–5). And in a recent book specifically devoted to South American archaeology (Silverman and Isbell, 2008), only 9 out of 51 articles referred to hunter-gatherers.

Conclusion

As Johnson (2014: 2) notes "Perhaps the most significant change in hunter-gatherer studies over the last several decades has been the shift from expecting hunter-gatherers to have similar properties (subsistence, settlement pattern, technology, social organization) wherever they are found to recognizing that hunter-gatherer adaptations should vary (often widely) along many different dimensions in different environments and under different levels of population density and regional organization diversity." After many years of "evolutionary paradigms dominating the discourse on hunter-gatherer variability and change" (Sassaman and Holly, 2011), the variability we expect to see among hunter-gatherers has begun to permeate the ways we construct our knowledge about them. Ingold's (2000) works were very influential in archaeology for expanding our view of hunter-gatherer diversity. His main critique is directed at attempts to apply models designed for the study of nonhuman foraging behavior to the analysis of human hunting and gathering. "This application results from a conflation of rational choice theory, drawn from classical microeconomics, with the theory of natural selection, drawn from evolutionary biology… A properly ecological account of hunting and gathering requires however that we dissolve this opposition, showing how people develop their skills and sensitivities through histories of continuing involvement with human and non-human constituents of their environments" (Ingold, 2000: 10). Also postprocessualists and interpretive archaeologists have begun to tackle hunter-gatherers (i.e., see above and Cannon, 2011). That diversity is reflected in a recent book which presents a wide array of theoretical stances (Cummings et al., 2014). As the middle ground claimed by Shott is still in construction, creative decades are coming for hunter-gatherer archaeology. Probably, the territory located at the great divide between Processualism and Postprocessualism will be the most fruitful.

Hunting and Gathering Societies: Anthropology

Nurit Bird-David, University of Haifa, Haifa, Israel

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The perspectives taken on the contemporary peoples referred to by this term have changed considerably since its early uses in the eighteenth century. I describe its evolving meanings, and then several clusters of features partially shared by these peoples, including sharing, perceptions of the environment, animism, relational knowledge, and relational ontologies. Though their cases are rare, they remain pivotal in modern thought as our ultimate 'Other' and our ultimate 'Us.'

'Hunting and gathering' is a conventional term for subsisting on the 'natural produce' of the earth by hunting and trapping wild animals; gathering wild roots, fruits, and berries; fishing; and collecting honey of wild bees, as opposed to producing food by agriculture and herding. By 'hunting and gathering societies' (HGS) ethnographers mean contemporary indigenous people who fully or partly engage in these activities, now or formerly, or who see themselves as hunters. (For brevity, the terms 'hunter-gatherers,' 'hunters,' and 'foragers' are sometimes used synonymously.) The term is also used in general reference to prehistoric populations, living before the agricultural revolution (around 10 000 years BP). In common usage, it also stands for alien Other, diversely constructed by modernity in order to define itself. In this article, the primary focus is placed on the first meaning, while note is taken of its brush with the other two. The term is first examined historically, with an outline of its origins and changes of usage over time. Then, several clusters of features that are partially shared by these societies are presented in model terms.

Contested Meanings

In order to understand the expanding meanings of HGS it is essential to go back to the origin of the field and follow its historical development. In the seventeenth century, writers invoked 'primitive peoples,' who hunt and gather for their subsistence, in discussing the 'natural state' of humankind. By the eighteenth century, these were typed 'hunter-gatherers,' in distinction from 'herders,' within a broad 'savage' class, in writings on the origins of property relations. In the nineteenth century, evolutionist work continued to draw on specific peoples, often without referring to the class as a whole, in studies of the origins of a variety of other social institutions, from kinship through politics to religion.

The notion consolidated as a central term in early twentieth-century cultural ecology theory, most influentially in Julian Steward's work (1936). Concerned with the relation between society and environment, Steward argued that for any given mode of subsistence, successful adaptation determines a certain level of sociocultural integration. In the case of hunting-gathering, he argued that this is a 'band,' which universally is patrilineal, exogamous, and territorial. HGS were associated with bands, and hunting peoples were comparatively studied as band societies (see, for example, Damas, 1969), until the 1966 symposium 'Man the Hunter' (Lee and DeVore, 1968). This interdisciplinary symposium commonly is considered the beginning of modern hunter-gatherer studies.

The symposium was inspired by the assertion that human beings had subsisted by hunting and gathering for over 99% of the time of human life on earth. Linking cultural-ecological and (neo)behavioral-evolutionary perspectives, its major objective was to learn about human origins and nature by comparing 'living hunters.' Uniform patterns found among them, it was posited, can be regarded as hunter-gatherers' successful adaptations, in present and past.

Serious reservations were raised about its agenda. One objection, for example, was that no contemporary group could be seen as 'living relics,' or as direct descendants, of the Pleistocene. Even if a group had been found to subsist purely on hunting, its people would have had a history as long as any other, and they would not have lived any longer in a world populated by hunters as in the Pleistocene. Another objection was that over the span of 2 000 000 years humans had changed considerably, biologically, and psychologically, enough to render homogenizing them inappropriate.

The ethnographic comparison, at the same time, profoundly overturned accepted wisdom. Contra Steward's persistent thesis, research revealed that most bands actually are socially fluid and nomadic. In many cases, gathering makes no less important contribution to subsistence than hunting. Contra contemporary stereotypes and bourgeois intuition, the comparison showed that these peoples meet their needs with surprisingly little labor. (Marshall Sahlins provocatively dubbed them 'the original affluent society.')

Outweighing the reservations, this successful outcome entangled HGS with 'Man the Hunter's' project. HGS came to mean a type of people, rather than diverse peoples engaged in a type of action, encompassing populations over a vast evolutionary span of time. The term now embodied the hypothesis that, at their core, these populations have similar sociocultural forms, determined by adaptation to the environment. From a fuzzy term of reference to 'very simple' peoples, and then to 'band societies,' it connoted a firm, homogenous and exclusive social category, a category of humanity defined techno-economically.

Subsequent ethnographic research, which burgeoned in the wake of 'Man the Hunter,' grew diverse in focus and approach, as seen, for example, in the series of International Conferences on Hunting and Gathering Societies (1978 to date, e.g., Leacock

 http://dx.doi.org/10.1016/B978-0-08-097086-8.12090-2

and Lee, 1980; Ingold et al., 1988[1986]: Vols. I, II; Burch and Ellana, 1994; Wenzel et al., 2000; Barnard, 2004). Issues arising from late twentieth-century indigenous circumstances and cultures were addressed, including political struggles and self-administration in modern states, and indigenous peoples' own perceptions of their environment, economy, and self. Historical, interpretative, regional, and applied perspectives commanded attention; evolutionary-ecological studies of foraging behavior increasingly took a separate course. Indigenous people started contributing to academic research, as anthropologists and interested parties. This growing ethnography showed a diversity of social forms among hunting-gathering peoples, from egalitarian to hierarchical and even slave-owning societies. The 1970s meaning of HGS as a firm, homogenous and exclusive social category was increasingly challenged. In an attempt to save it, the category was diversely divided into subtypes (e.g., see Woodburn, 1982). Or, it was recharacterized, for example, by a collective appropriation of nature (see Ingold, 1986), and by distinct cultural perceptions of the environment (see Bird-David, 1990, 1999; Ingold, 2000).

The 1980s and the early 1990s saw many controversies, sparked partially by inflexible readings of the term HGS. Scholars disputed the category as pertaining to a class of societies that are both singularized by hunting-gathering and distinguished from agricultural and pastoral peoples, because the ethnography revealed continuities between hunter-gatherers and other societies, as well as a great diversity among the hunter-gatherers themselves. Other scholars questioned the categorization of societies by mode of subsistence, as research showed heterogeneous and changing economies. Hunting-gathering was found to be articulated with other pursuits, going back in some cases centuries and even millennia, and, at any rate, under speeding changes since the mid-twentieth century. Students debated whether any living group sufficiently complies with the subsistence criterion and whether this criterion generates a meaningful category, one whose members share more than the selecting mode of subsistence. Even the field at large was critiqued as spurious, by researchers seeing it in terms of the 1960s objective to learn about prehistory and evolution. Their criticism drew on ethnohistorical and archeological work suggesting arguably that these societies have not escaped the world and regional forces.

The new millennium has seen a surge of renewed interest in hunter-gatherers' studies, and once again their discussions in interdisciplinary forums bringing together the four fields of anthropology. The diversity of HGS is addressed, accommodating within the category the assemblage of indigenous peoples discussed by practitioners within the field of hunter-gatherer studies (see Kelly, 1995). Attention is paid not only to their diversity but also – through such issues as their relations with others, the changes they undergo, and their socialities and ontologies – to both their resilience and vulnerability.

HGS, then, is a historically situated term, which has acquired multiple layers of meanings over the years. It is a circumlocution for a historically situated field of research that provides a stimulating comparative context and a scholarly communal framework within which to explore a broad array of distinctive issues. Ethnographers construct 'partial connections' (in Strathern's sense of the term, 1991) between these societies by studying their respective groups while keeping the others 'in mind.' They call to attention partially shared features, which determine common issues in the field, and contribute distinctive perspectives to anthropology, generally. Hunting and gathering activities are a focus of attention, rather than a criterion of demarcation, for scholars and for the indigenous peoples themselves.

Issues

This section presents, in model terms, some of the partially shared features that came to light in the course of ethnographers' comparative discussions of their field experiences and material.

Hunting and Gathering

In many of these societies, people combine these activities with other economic pursuits (e.g., trade in minor forest produce, horticulture, work for neighbors, wage labor, social benefits, etc.). However, hunting and gathering themselves carry special significance; they are a total phenomenon encompassing economic, social, and symbolic aspects. Hunting-gathering, moreover, often influences the way in which people carry out such other activities. They often return to hunt and gather at least periodically, when not prevented from doing so. They regard what they collect as 'real food,' and while they do pursue other activities, in some cases, hunting-gathering still provides a major part of their diet. Some postforagers return to their traditional lands in attempts to creatively combine traditional and modern lifeways.

Band Society

In many of these societies people live in small groups (described in early work as 'bands') consisting of several families. The groups are flexible and fluid. Making visits, and even shifting residence, from place to place, are common, including in new modern settlements, and highly valued. Men and women often know each other personally; they all are (or at least are classified as) family and relatives. Their sense of themselves as family often survives growing integration into nation-states.

Sharing

The land and its resources in many of these societies are often collectively appropriated (Ingold, 1986). Their sharing cannot be understood as a form of exchange (Woodburn, 1998) but as a core part of their modes of sociality (Bird-David, 1994). Game is publicly shared; other resources are shared in response to direct demand for sharing (Peterson, 1993), especially foraged resources. Sharing and the expectation of it is part of broader nonaggrandizing economic reasoning and conduct. While hard to express in modern urbanite language, sharing extends not only to distributive but also to social experience. People in the group share each other: they share company, dwelling spaces and work, stories, memories, and

personal histories. They experience their selves as coalescent, rather than as a group of separate individuals, with cultural priority given to immediate relations (Bird-David, 1994). Sharing, which is normatively promoted, fosters an egalitarian society in many cases (see Woodburn, 1982). While closely connected, people usually enjoy considerable personal autonomy.

Giving Environment, Animism, Relational Epistemology, and Conservation

Nature is locally experienced neither as a mechanical system nor as objects for human use and ownership, but as an assembly of sentient beings related to and shared with (Bird-David, 1990). These beings (animals, forest, winds, hills, etc.) are frequently approached as relatives, often as grandparents. People care for them, and this helps sustain their collective identity. People engage with these beings through shamanistic practices and by pursuing hunting-gathering. To hunt and to gather are perceived not just as subsistence pursuits but also as means of communication with the 'natural' relatives. Even when forced to reside away, and to adopt modern lifestyles, people commonly practice their rituals, and return to their places to hunt-gather and 'keep in touch' with their relatives. This animistic perception is integrated with deep ecological understanding of the neighborhood. It often propagates responsiveness to and responsibility for constituents of the environment, along with its utilization (Bird-David, 1999), however, with conservationist effect limited to certain situations (Bird-David and Naveh, 2008).

Relations with Others

With the benefit of growing understandings of HGS themselves, attention has expanded to their relations with others, including traditional agricultural neighbors, ancient civilizations, and modern states. In many parts of the world, HGS have been living for centuries if not millennia not just in contact with others but in symbiotic relations with their neighbors, arguably as equal to or dependent on them (see Ikeya et al., 2009). Tropical forest hunter-gatherers of Central Africa (alias Pygmies) are known for their close ties with cultivators, and for links of fictive kinship and patron–client relations with them. Southeast Asian groups are known for close trade links between foragers and farmers, and historical shifts back and forth between foraging and shifting cultivation. South Asian foragers, as now newly appreciated, have maintained their foraging lifeways for millennia amidst Hindu civilizations (Gardner, 2013). HGS's conflicts, resistance, and self-determination in both developed and developing nation-societies, such as Canada, Australia, and Botswana, are extensively studied (Biesele et al., 1999).

Hunter-Gatherers' Ontologies

The 2000s surge of interest in indigenous ontologies, responding to the general 'ontological turn' in anthropology, has rejuvenated interest in hunter-gatherers' relational ontologies. Their ways of being human, and their relations with humans, nonhumans, and ancestors – as conceived, lived, experienced, and acted upon – are given serious attention as ontological potentialities. In the booming study of the indigenous ontologies, HGS are sometimes discussed together with other small-scale indigenous peoples such as, for example, Amazonian peoples. The pendulum may have swung too sharply to the opposite end, overlooking some possibly distinctive hunter-gatherers' ontological senses amidst general commonalities. HGS's worlds are often constitutive of relations of sharing and living together with humans and nonhumans, present and ancestral, and with their lands. Experienced relations suggest the ontological status of an interlocutor as subject or, at times, object premising that everything has ontological potentiality for communication. The ontological boundary between subject and object, human and nonhuman, is permeable, variable, and negotiable (see Poirier, 2013).

Conclusions

Once the world's sole inhabitants, HGS constitute now only a tiny fraction of the modern world population. Yet, they remain resilient as well as vulnerable, with surprisingly many groups still unstudied, especially in Central Africa and South Asia (see Fortier, 2009 on the latter). Their lives have been changing over the past 150 years during which they have been the subject of anthropological interest. But the perspectives that anthropologists have been taking on them during these years have changed more profoundly. HGS have found ways of partially continuing and renewing their hunting-gathering traditions, and their modes of sociality and ontologies, despite extraordinary pressures and violence, during these 150 years. Anthropologists have dramatically changed their perspectives on HGS: from regarding them in the nineteenth century as savages and creatures of nature – through approaching their lifeways in the early twentieth century as cultural-ecological adaptations to nature, and in the mid-twentieth century as cases from which to learn about human evolution and prehistory – now, to seriously addressing and learning from them alternative senses of nature and ontological potentialities.

Though their cases are rare, HGS continue to creatively help us think about a whole range of key issues, including socio-environmental ethics and praxis, child care and gender, conceptions of society and nature, human relationships and sharing economies, showing us markedly different ways from familiar models. In broadening scholars' imagination, that cannot but be biased by urban life experiences and intuitions, HGS can help scholars think about other forms of life: human life in the past as well as possible futures. HGS remain pivotal in modern thought as our ultimate 'Other' and our ultimate 'Us.'

Abstract

Samuel Phillips Huntington was an influential American political scientist. He was also a consultant to various American government agencies. He upholds the idea of conservative realism in politics. His research covers several areas of political science, such as civil–military relations, modernization and political development, comparative politics, and international relations. Regarding the role of military, he argues for autonomous military professionalism. In discussing about modernization of developing countries, he emphasizes the priority of political order over democracy. In the case of America, as well as other democratizing countries, he worries that the excess of political participation would diminish the authority and effectiveness of state governance, enhancing political instability, and, at worst, leading to the reverse of democratization. After the end of the Cold War, Huntington characterizes the international order as multicivilizational, in which the clash of civilizations will direct the development of global politics. In such a multicultural situation, Huntington urges Americans to affirm their unique national identity by revitalizing Anglo-Protestant culture and its religiosity, which has defined America since its founding.

Biography

Samuel Phillips Huntington was a prominent American political scientist. He was born in 1927 and brought up in a middle-class family in New York City. His father, Richard Thomas Huntington, was a publisher of a tourist magazine, and his mother, Dorothy Sanborn (née Phillips) was a short-story novelist. Huntington was the only son. He studied at Peter Stuyvesant High School. He wrote poetry when he was still a youth. At 16 years of age, he entered the Yale University, and has graduated with 'exceptional distinction' at 18 years of age; and then served in the US Army. In 1948, he acquired master's degree in political science from the University of Chicago.

In 1951, he was awarded a doctorate by Harvard University, where he finished his PhD dissertation in 4 months. He believed that his rapid completion of dissertation precipitated his diabetes, by which he need to administer himself three daily insulin injections ever since. During his study in Harvard University, he began teaching at 23 years of age in 1950. In 1957, his first important book, *The Soldier and the State: The Theory and Politics of Civil–Military Relations*, was published. This book brought to him widespread vehement attacks. Huntington's argument for the military professionalism in this book was considered by some senior professors in Harvard as a laudation to militarism, and Huntington was denied tenure in 1959. He then went to Columbia University as an associate professor of government and a deputy director of its Institute of War and Peace Studies. His two other books on military politics, *The Common Defense: Strategic Programs in National Politics* and *Changing Patterns of Military Politics* were then published respectively in 1961 and 1962.

In 1963, Huntington was asked to return to Harvard as a tenured professor of government. He then, coauthored with Zbigniew Brzezinski, his old Harvard colleague, and published *Political Power: USA–USSR* (1964), which was to compare the political systems in the US and the Soviet Union. In 1965, he became a fellow of the American Academy of Arts and Sciences.

In 1967, Huntington worked in Johnson Administration and wrote a 100-page report on the Vietnam War, *The Bases for Accommodation*, published in 1968b *Foreign Affairs*. In the article, while Huntington supported America to defeat North Vietnam, he criticized America for endorsing wrong strategy. To win the Vietnam War, Huntington argued for a strategy of 'forced draft urbanization,' a strategy of carpet bombing the rural countryside and to force the rural population moving into city; thus, weakening the support of the Vietcong by the ethnic and communal network in rural areas. However, the article caused students' tremendous protest. His office, the Center for International Affairs, was firebombed. The words "War Criminal Lives Here" were painted on his house front door.

At the same year, another important book, *Political Order in Changing Societies* (1968a), was published. In 1970, he published an edited volume, *Authoritarian Politics in Modern Society: The Dynamics of Established One-Party Systems*, which argued for durability of authoritarian politics. And *No Easy Choice: Political Participation in Developing Countries*, coauthored with *Joan M. Nelson*, was also published in 1976. These three books are considered as Huntington's important works on political development in developing countries, demonstrating his persistent thesis: If political participation outstrips institutionalization, political decay instead of development will result. His writings on political development and the Vietnam War built his reputation as a conservative hawk.

In 1970, Huntington cofounded the prominent *Foreign Policy* magazine with Warren Demian Manshel. Huntington remained as coeditor until 1977. In this time, he published two books about the instability of American democracy due to excessive political participation: *The Crisis of Democracy: Report on the Governability of Democracies to the Trilateral Commission* (1975), coauthored with Michel Crozier and Joji Watanuki, and *American Politics: The Promise of Disharmony* (1981).

During 1977 and 1978, Huntington was invited by Zbigniew Brzezinski, at that time President Carter's National Security Adviser, to work at the Carter White House as

 http://dx.doi.org/10.1016/B978-0-08-097086-8.61219-9

coordinator of security planning for the National Security Council. He authored Presidential Directive 18 (PD-18), 'US National Strategy,' an analysis of US–Soviet strategic competition. He predicted that the ideological and military threat posed by the Soviet Union was just temporarily, the US would finally win. He suggested the US to expand the military power and to dispose the Rapid Deployment Force in the Persian Gulf to protect the region from Soviet intrusion. Huntington's analysis helped to inform the foreign policy from Carter administration to Reagan government.

In the 1980s, he became a member of the Presidential Commission on Long-Term Integrated Strategy. He also served as director of Harvard's Center for International Affairs from 1978 to 1989, and as president of the American Political Science Association from 1986 to 1987. In 1989, he started the John M. Olin Institute for Strategic Studies, and was its director until 1999. In this period, he has published *American Military Strategy* (1986).

The end of the Cold War further shaped Huntington's thought on the new international order and the US role in it. In *The Third Wave: Democratization in the Late Twentieth Century* (1991), he explored the features of third-wave democracy movement and demonstrates factors that advance or reverse the trend of democratization in the developing countries. He also listed the political, cultural, and economic obstacles to democratization. In particular, he discussed Confucianism and Islamic faith, and their relation with democratization in different countries in East Asia and the Middle East. The exploration of cultural obstacle of democratization seemed to pave the way to his most famous thesis 'The Clash of Civilizations and the Remaking of World Order,' which appeared in a 1993 *Foreign Affairs* article and in the 1996 book of the same title. These two books, as well as his earlier writing on political development, critically refute the over optimism about the universality of democracy assumed by many American scholars, especially associated with the thesis of 'End of History' posed by Francis Fukuyama in 1989. After the publication of the article, he served as chairman of the Harvard Academy for International and Area Studies from 1996 to 2004. In this period, he had published *Who Are We?: The Challenges to America's National Identity* (2004). He also involved in editing several books with other scholars on topics about military, political development, globalization, and culture.

Huntington died on 24 December 2008, Martha's Vineyard, 81 years of age. He married with Nancy Arkelyan Huntington for 51 years and they have got two sons. He was a self-declared conservative and a lifelong democrat, but an old-fashioned one. He claimed himself as a follower of Reinhold Niebuhr, the leading Protestant theologian of twentieth-century America.

Main Writings

The Soldier and the State: The Theory and Politics of Civil–Military Relations

This book was partly provoked by the firing of General Douglas MacArthur by President Harry Truman in the Korean War. The event inspired him to explore the civil–military relations in a liberal democratic society. Before, as civil–military relations are expected to be compatible with American liberalism, people used to endorse liberal idea of subjective civilian control that requires the military to involve in institutional politics, thus military's autonomy is legally and institutionally restricted. However, Huntington, in this book, argues for the theory of objective civilian control, which stresses "autonomous military professionalism" (Huntington, 1957: 83), and endorses conservatives, anti-individualistic ethos. While civilian officials make decision on policies, we should let military to have autonomy in all technical, professional matters, so that the military can work out the means to execute the policies. Huntington thinks that professionalizing military can best serve the security of American nation, instead of democratic force.

Huntington first provides a historical and theoretical analysis of officership as a profession, and argues that the expertise of the military officer is "the management of violence" (Huntington, 1957: 11). Liberalism believes in individualism, have faith in human capacity for advancement, and distrusts in power and military. For Huntington, such a view is too optimistic. Conservative realism rather believes "the permanence, irrationality, weakness, and evil in human nature" (Huntington, 1957: 79). The origin of violence lies in selfishness and weakness of human nature that can only be controlled by "organization, discipline, and leadership" (Huntington, 1957: 63). Military ethics stresses the importance of order and power in sustaining state security. It emphasizes the priority of community over individual, as individuals can only realize themselves by participating in the great continuing organic body. Thus, "[t]he military ethic is basically corporative in spirit" (Huntington, 1957: 64). Then, Huntington argues that the practice of soldier is a professional matter. An efficient society should leave room to soldiers to cultivate their professional abilities and have their own professional ethic. He reviews the prevalence of liberalism and the arduous development of the professionalism in the history of America from 1789 to World War II (WWII). He shows that the constant suspicion of professionalism by liberalism that had repeatedly attempted to 'enlighten' the soldiers, and thus reducing the efficiency of the military, which indeed threatens the security of the nation.

Finally, Huntington explores the civil–military relations during and after the WWII. In his analysis of the political roles of the Joint Chiefs and the Department of Defense, Huntington points out that the shortcomings of these institutions lie in the liberal ideology, which makes people to be unrealistic in thinking about war. Huntington, therefore, urges to abandon liberalism for military professionalism that is required in the coming age. The book is ended by adoring the elite military college at West Point.

Political Order in Changing Societies

In this book, Huntington argues for the priority of political order and stability over individual liberty in political development. In his studies of international politics during the 1950s and 1960s, Huntington notices a dramatically growth of incidence of political violence and a decline of political order in many modernizing countries. By using historical

comparative analysis of these different political orders, he shows that the political instabilities are not because of impoverished economy or backward politics and culture; rather they are largely due to the fast social change and mass political participation that come with the slow progress of political institution. Americans are blind by their happy history. They usually assume that all the goodness, such as democracy, economic development, and social justice, would automatically come together in modernization. However, it is not the case in many modernizing countries because of their different histories, geographies, and social conditions. Thus, he argues that for these developing countries, the primary concern is not about liberty; rather it is the question of how to establish a legitimate political order. He states, "Men may, of course, have order without liberty, but they cannot have liberty without order" (Huntington, 1968a: 7–8).

In these modernizing countries, the rise of economic growth and the living standard, and the literacy of people, coupled with the spread of Western values, led to the aspiration of political participation. Through political participation, socially mobilized individuals expressed their demands to their government. However, as these governments were low-level institutionalized, and the new values were resisted by traditional groups with deep-rooted privilege, the demands upon government were hard to be expressed in legitimate way and to be gathered within the political system. Thus, the rise of political participation engenders political instability.

For Huntington, the key to social stability is a strong political institution, which can respond political participation by social forces from different groups. Political institution is about political organization and procedure of administration, which aims at "maintaining order, resolving disputes, selecting authoritative leaders, and thus promoting community among two or more social forces" (Huntington, 1968a: 8–9). It can be measured by its adaptability, complexity, autonomy, and coherence. The more the adaptable, complicated, independent from other social forces, and coherent an organization is, the more highly institutionalized it is.

Huntington's discussion about military intervention in politics is especially interesting to many scholars. Instead of assuming the fondness of military to interrupt, the political intervention of these specialize social groups usually due to "the absence of effective political institutions capable of mediating, refining, and moderating group political action" (Huntington, 1968a: 196). Huntington calls this as "the praetorian society" (Huntington, 1968a: 195). As the society is lacking agreements among groups, public recognized political leaders or legitimate intermediaries to moderate conflicts between social forces, there would be different kinds of direct political participation. "The wealthy bribe; students riot; workers strike; mobs demonstrate; and the military coup" (Huntington, 1968a: 196). The method of military intervention is simply more dramatic and more effective to arbitrate the conflicts than others. Generally speaking, the military prefer to take the role of guardian, avoiding dangerous components brought into power of governors. If the military must govern, their leaders tend to be conservative. They usually resist to reform and to assimilate the newly politicized groups that the society requires. It makes those groups become the resentful enemies of the country.

Thus, for Huntington, military regimes are good at concentrating power and executing political reform, they are also strong in extending power to the urban middle class; but they are impotent in dealing with the complicated society, in coordinating and aggregating interests of different groups. Thus, Huntington suggests to "convert military intervention in politics into military participation in politics" (Huntington, 1968a: 243), which assimilates urban elites into politics while limits their political participation, so that the social and economic reforms are protected from traditional forces in the society.

Furthermore, the political reform must be slow and gradual. Historically speaking, the attempts of radical political reforms usually failed, because it would cause too much resistance from different parties. Instead, Huntington suggests the strategy of the "proper mix of Fabianism and blitzkrieg" (Huntington, 1968a: 346). It means that the reform cannot be fast; it should be step by step, drafted in relative secrecy and working on only one issue at a time. Once the time is right, the issue must be rapidly resolved, and then to erase it from the political agenda before the protest has been lodged by the opponents.

The Crisis of Democracy

In 1960s, there were many different kinds of social movements in America such as movement for civil rights, antiwar, feminism and sex liberation, etc. Popular participation has greatly increased, and authority of existing systems was challenged. The predominance of equality as a social, political, and economic goal was reasserted. For Huntington, the 1960s was "a decade of democratic surge and of the reassertion of democratic egalitarianism" (Crozier et al., 1975: 60). The immediate influence on government of democratic surge is contradictory: "The vitality of democracy in the United States in the 1960s produced a substantial increase in governmental activity and a substantial decrease in governmental authority" (Crozier et al., 1975: 64). Decline in governmental authority with high social expectation and mass political participation causes, what Huntington calls, "democratic distemper" (Crozier et al., 1975: 102), a threat to political stability. The distemper, for Huntington, stems from an "excess of democracy" (Crozier et al., 1975: 113). The remedy is not to have more democracy, but to restore balance between governmental activity and governmental authority, that is also "to restore balance between vitality and governability in the democratic system" (Crozier et al., 1975: 113). To achieve this moderation, we have to acknowledge two points. First, democracy is only one method of constituting authority; it is neither the only method nor the universal one. Sometimes, "the claims of expertise, seniority, experience, and special talents may override the claims of democracy as a way of constituting authority" (Crozier et al., 1975: 113). Second, the successful operation of democracy requires certain intervention from the state, and indifference and noninterference of political groups. If the political requirements have exceeded what the political institution can offer, the political authority may be damaged. Huntington, therefore, concludes that

although democracy is generally recognized as a good, it also has a limit; to maximize it is not always a good thing to do.

American Politics: The Promise of Disharmony

In this book, Huntington questions, why contemporary Americans are so rebellious, while most people in history usually conform to convention and follow rules. Huntington thinks that Americans, in the 1960s and 1970s, have experienced a period of creedal passion, in which people were aware of a gap between American ideal and its institutions with the atmosphere of discontent, and hence the political participation increases. He has also demonstrated three other creedal passion periods such as the American Revolution, the Jacksonian Era, and the Progressive Era. Different from other continental countries, Americans perceive their national identity as not defined by ethnics, heritage, or certain organic characteristic, but by political ideals. Huntington calls these ideals the 'American Creed,' which stresses democracy, equality, liberty, constitutionalism, and individualism. However, in reality, political institution inevitably attempts to maintain the political order involving a set of interests and certain restrains on freedom. This induces a permanent gap between ideals and institutions; Huntington calls it the 'IvI gap,' which leads to tension and disharmony in American politics. Americans' responses to the gap have shown a 'consciousness cycle' from moralism, cynicism, complacency to hypocrisy. At times, people have a highly intensity of belief in the ideals with a clear perception of the gap; they would respond in a moralistic way that attempts to eliminate the gap by changing the political system and reducing the power of government. When people find that the reform is impossible to achieve, they turn into cynicism and endure the gap. Cynicism then becomes complacency by denying the gap to deal with the cognitive dissonance, and finally develops into hypocrisy and ignores the gap. After a period, moralism will be reinvigorated. The cycle of creedal passion periods seems to happen about every 60 years. Huntington expects that the cycle would probably be continued. Nevertheless, because of continuing political development and America's increasing engagement in the international politics, a large complicated political institution is required. Huntington, therefore, argues that Americans should make a balance in the search of ideal and the political development. Although many critics find that America is a lie since its reality is far from its ideals, Huntington disagrees. He states, "America is not a lie; it is a disappointment. But it can be a disappointment only because it is also a hope" (Huntington, 1981: 262).

The Third Wave: Democratization in the Late Twentieth Century

In this book, Huntington identifies three waves of global democratization. The first started from Jacksonian democracy in the US in 1820s, and then extended up to 29 democracies in 1926. However, the rise of Mussolini in Italy started the first reverse wave that reduced democratic states down to 12 in the world. The second began with the triumph of the Allies in the WWII that reached 36 democratic countries in 1962, but back down to 30 in the second reverse wave during 1960–75. The third wave started from 1974 up to the time Huntington writing the book, meanwhile there are more than 30 countries making transition to democracy. This book mainly focuses on the study of the third-wave democracy by comparative approach.

Huntington has listed five common factors that have given rise to the occurrence of the third-wave democratization: (1) the aggravating legitimate crisis of authoritarian regimes by widespread of democratic values and the economic failure, (2) the fast global economic growth of the 1960s, which increases people's living standards and the growth of urban middle class, (3) the expansion of Christianity in the third-wave democracy and the alternation of attitude toward democracy by the Catholic Church, shown in the Second Vatican Council and the National Catholic churches' opposition toward authoritarianism, (4) the influence from the new policy of the external actors, such as the policy shift of the Soviet Union, and the promotion of human rights and democracy by European Community and the United States, and (5) the snowballing effect by successful democratization of other countries, especially to those countries that are geographically close and culturally similar.

Based on the experience of the last two reverse waves, Huntington also anticipates three factors that are likely to cause a third reverse wave: (1) Democratic states' failure of effective operation could undermine their own legitimacy, especially in the face of international economic crisis. (2) The reverse development from democracy to authoritarianism and dictatorship by nearby states, or the rise of power of nondemocratic states can also have reverse snowballing effect. (3) Different old and new forms of authoritarianism may emerge that meet the need of the time.

Finally, Huntington has discussed political, cultural, and economic obstacles to democratization. Economically, poverty is probably the main obstacle to democratization. The "transitions to democracy should occur primarily in countries at the middle levels of economic development" (Huntington, 1991: 60). Politically, the lack of experience with democracy and the existence of long-term authoritarian ruler would hamper the democratic development. Culturally, Huntington states, "[a] profoundly antidemocratic culture would impede the spread of democratic norms in the society, deny legitimacy to democratic institutions, and thus greatly complicate if not prevent the emergence and effective functioning of those institutions" (Huntington, 1991: 298). In particular, he discusses Confucianism in the East Asia countries and Islamic faith in the Middle East, elaborating how these traditions have various influences to the development of democracy in different countries. Basically, Huntington believes that the interaction between the cultural tradition and the social development is complicated. Furthermore, "cultures historically are dynamic rather than passive. The dominant beliefs and attitudes in a society change" (Huntington, 1991: 311). Therefore, these cultural obstacles are not necessarily preventing democratic development.

The Clash of Civilizations and the Remaking of World Order

With the end of the Cold War, Huntington claims, the international order has changed. For the first time in history, "global

politics has become multipolar and multicivilizational" (Huntington, 1996: 21). The primary distinctions among people in this new world are no longer ideological or economic, but cultural. The main thesis of this book is to show that cultural identity, or civilizational identities at the broadest level, are shaping the global political order in the post-Cold War world (Huntington, 1996: 20). By 'civilization,' Huntington means "a culture writ large" (Huntington, 1996: 41), "the highest cultural grouping of people and the broadest level of cultural identity" (Huntington, 1996: 43). He has identified eight existing civilizations: Sinic, Japanese, Islamic, Hindu, Slavic-Orthodox, Western, Latin America, and African. In the new international order, the interaction among states will be multidirectional, shaped by power and wealth, as well as their cultural preference and religion. The clash of civilizations will direct the global politics in the future. He also argues that modernization is not necessarily Westernization. The attempt to establish a universal civilization by the West is a kind of Western cultural hegemony. It is also the source of "the resentment and hostility of non-Western peoples against the West" (Huntington, 1996: 59).

As the influence of the West is declining, the balance of global power has shifted. The West has to face the increasing challenge from other civilizations that want to shape the world in non-Western style. Asian civilizations are enlarging their political, military, and economic strength; Islamic countries have experienced rapid growth in population and expanded religious ideology. The revitalization of Islam "embodies the acceptance of modernity, rejection of Western culture, and the recommitment to Islam as the guide to life in the modern world" (Huntington, 1996: 110). These non-Western civilizations generally maintain the values of their own religion and culture, and posed the threat to the Western civilization. It also shows that the world is becoming modernized without being Westernized.

Huntington predicts that the idea of Universalism by the West will cause growing clashes with other civilizations. He anticipates that the clashes with China and Muslim countries would be the most serious. An alignment between Muslim and Sinic cultures may be formed to fight against their common enemy, the West. Huntington has identified three cases by the West that would be perceived by non-Western countries as the attempt to enforce the Western cultural hegemony: (1) the proliferation of weapons to maintain military superiority, (2) the promotion of human rights and democracy, and (3) the restriction of non-Western immigration.

Furthermore, the conflicts at the local fault line, mainly between Muslims and non-Muslims, would create a "kin-country syndrome" (Huntington, 1996: 254) whereas states of a civilization would mobilize support from states of their civilization in the war against another civilization, their common foe. It would escalate the threat broader, and thus the core states would give effort to stop these wars.

The world is now inevitably multicultural. The United States and the West are facing both internal and external challenges. The internal is the declining of the Western values. The external is the rising of the non-Western cultural identities. On the one hand, Huntington suggests the West to recognize the fact of multicivilizational international order, to enhance the understanding of the religious and philosophical assumptions underlying other civilizations, and to identify commonalities among Western and other civilizations. On the other hand, Huntington believes that the endurance of the West depends on Americans' reaffirming their recognition of the West. So Americans have to perceive the Western civilization as a unique, not universal; to consolidate and to renew their own culture. This idea has also motivated him to write the following book, to explore the nature of American identity.

Who Are We?: The Challenges to America's National Identity

For Huntington, Americans are facing the identity crisis; the United States is under the threat of disintegration. In this book, he argues for the revitalization of America by reembracing "the cultural core" (Huntington, 2004: 59): the Anglo-Protestant culture, values, and religious commitment, without the elements of race and ethnicity.

In the book, Huntington refutes two widely accepted theses: (1) America is an immigrant nation and (2) American identity is solely defined by the American Creed. Huntington examines the history and argues that the America's founders in the eighteenth century should be considered as settlers rather than immigrants. They are not immigrants because they have founded a new polity with a distinct culture rather than arriving in an existing one. Thus, the origin of America was not "a nation of immigrants" (Huntington, 2004: 37). Rather it was a nation established by the Anglo-Saxons with core national culture: English and Anglo-Protestantism. In the nineteenth century, the substance of American national identity includes four elements: race (white), ethnic (Anglo-Saxon), religious culture (Anglo-Protestantism and English), and ideology (American Creed). For Huntington, America would not be the America today if it was not founded "by British Protestant, but by French, Spanish, or Portuguese Catholics … it would be Quebec, Mexico, or Brazil" (Huntington, 2004: 59).

After the United States has been established by the Anglo-Saxons, wave after wave of immigrants have attended, joined the settlement, and assimilated by the institutions, language, and culture of the core nation. This has also weakened the elements of ethnic and race in defining American identity. For Huntington, the main challenge was the mass immigration from Mexican with the Hispanic 'culture of Catholicism' in the Southwestern America in 1970s (Huntington, 2004: 254). They are different from previous immigrants because they want to maintain their own culture and are unwilling to be assimilated. At the same time, the universities and intellectuals started to embrace multiculturalism and criticized against the Anglo-Protestantism. Huntington worries that the reluctance to be assimilated by Hispanics could lead to "a bifurcated America, with two languages, Spanish and English, and two cultures, Anglo-Protestant and Hispanic" (Huntington, 2004: xvi). Indeed, apart from the rise of multiculturalism, the American national identity is also threatened by the globalization of business, professional and academic elites, the effect of diasporas, and the collapse of the Soviet Union, which left America lost the enemy against which to define itself.

Given the fact of multicultural situation, many liberal elites suggest to sustain the solidarity of the United States by embracing the American Creed. However, for Huntington, simply relying on the American Creed or any civic ideology is

too thin to maintain a nation for long. In the past, few nations have ever been successfully defined solely by a set of political principles. Some communist states, such as the Soviet Union, Yugoslavia, and Czechoslovakia, that attempted to use ideology alone to unite people of different cultures, have finally collapsed. On the contrary, the declining of communist ideology in China, with a core Han culture, has posed no threat to the solidarity of a country. Apart from ideology, identity must contain other substances such as shared emotion, language, memory, and culture. In particular, the 'core' Anglo-Protestant culture, which has been upheld by American of all races, ethnicities, and religions, is indispensable for American national identity. Indeed, the values of American Creed are not abstract and universal; they are also the product of the Anglo-Protestantism. Once the Anglo-Protestantism is rejected, and thus the American Creed is separated from its origin, the emotional and psychological force of the Creed would also be diminished. In the face of powers from different civilizations and countries, Huntington rejects the idea of cosmopolitanism, which opens America to be reshaped by other people and cultures. He also refutes the idea of imperialism, which attempts to use American power to reshape the world according to American values. Rather, Huntington suggests the nationalist approach, which recognizes and accepts the distinctiveness of America from other countries. The difference between America and other countries is largely defined by its Anglo-Protestant culture and its religiosity. Americans should strengthen the American identity, preserve and revitalize their culture that has defined America since its founding.

His Influence

Huntington is described as "[o]ne of the most influential political scientists of the last 50 years" by Corydon Ireland in Harvard News Office. He has established a new model of analyses of international and domestic conflicts. He also served as a mentor to dozens of famous policy makers and intellectuals such as Francis Fukuyama, the author of *The End of History and the Last Man* (1992), and Fareed Zakaria, the former managing editor of *Foreign Affairs* and the current editor of *Newsweek International*. His writings have shaped American views on civilian–military relations, democracy, modernization, political development, comparative government, and international relationship. His *The Soldier and the State*, in its 15th printing, is still considered a standard title about how military affairs interact with the political realm. The book *Political Order in Changing Societies* is also frequently reprinted, most recently in 2006. It remains the requisite reading for political science students today. In particular, after 9/11 terrorist attack, his *The Clash of Civilizations* is applauded as prescient to the global conflict of cultures, and has shaped recurrent debates on international relations. The book was translated into 33 languages; there also exists a pirated translation in Iran. The book shows a critique to those who thought the end of the Cold War meant the universal triumph of Western values.

Abstract

James Willard Hurst was the most influential American legal history scholar. This article examines his professional and personal life and addresses his lasting impact. Rather than focusing on the opinions of appellate courts, Hurst looked to the practical, everyday influences of law and lawyers and pioneered a new approach to American legal history.

J. Willard Hurst of the University of Wisconsin was the most influential scholar within the realm of American legal history. By emphasizing factors beyond legal doctrine and by altering the way people think about time, place, and change itself, Hurst enlivened and transformed an entire academic field. Doing legal history from the outside – from the perspective of sociological jurisprudence – led Hurst to turn his back on the 'great man' tradition and to reject the previously dominant focus on formal judicial opinions. He firmly opposed teleological accounts that tended to celebrate the gradual improvement of law over time. Instead, Hurst focused on economic matters, as shaped by the general culture, and on the ordinary processes of statutes, administrators, unremarkable cases, and the everyday work of lawyers. In particular, Hurst concentrated on tracking what he termed 'the expansion of middle-class energy,' which he called 'our prime inheritance.'

Throughout his decades of scholarship, teaching, and mentoring, Hurst combined careful and unremitting attention to massive low-level details with sweeping descriptions of general patterns. Hurst not only redefined an entire academic field, but he also did a great deal to open the borders of legal history to other disciplines. As leading legal historian Lawrence Friedman said: "Willard Hurst, as a scholar, did what few scholars have ever succeeded in doing: he created a whole new field of study, and virtually out of nothing" (Friedman, 1965).

Biographical Background

James Willard Hurst was born on 6 October 1910 in Rockford, Illinois, where his father ran a movie theater and had other business interests. When Hurst attended Williams College from 1928 to 1932, he majored in economics, and became editor in chief of the student newspaper and president of the International Affairs Club. He graduated Phi Beta Kappa and wrote a prize-winning student essay on international implications of the English Gold Clause crisis of 1931, published in the *Journal of Political Economy* (Hurst, 1932). Hurst then attended Harvard Law School, and reported that he was disgruntled about the emphasis on abstractions and the failure to pay attention to the depression and to the ideas of the legal realists. A Note Editor of the *Harvard Law Review*, Hurst graduated in 1934 and spent the 1935–36 academic year as a research fellow for Felix Frankfurter, working primarily on the lecture series Frankfurter published as *The Commerce Clause under Marshall, Taney, and Waite* (Frankfurter, 1937).

Hurst next served as law clerk for 80-year-old United States Supreme Court Justice Louis D. Brandeis during the 1936 term, one of that Court's most contentious ever. Brandeis thought the states to be invaluable laboratories for progressive regulation and lawmaking, and he urged young men who worked for him to return to their home regions. Hurst became one of the very few to heed Brandeis's advice. In 1937, Hurst declined an invitation to teach at Yale, instead choosing to teach at the University of Wisconsin, not far from his hometown. The fact that the law school was connected to the rest of the University appealed to Hurst – it was easy to work together with people in economics, sociology, and ultimately, the history department (Garth and Sterling, 1998). In the course of rejecting the offer from Yale, Hurst wrote to Frankfurter that Wisconsin afforded 'just about an ideal 'laboratory' situation.' Despite Yale's offer of higher rank and double the salary, Hurst advised Frankfurter that he preferred Madison, Wisconsin, 'particularly because of this extraordinarily interesting state government machinery here on the doorstep' (Soifer, 1992).

By 1941, Hurst had compiled several books of teaching materials and coauthored *Law in Society* (Hurst and Garrison, 1941) with his dean, Lloyd Garrison. This pioneering casebook focused on the myriad ways that the plight of a widow – a woman whose husband, a carnival worker, was crushed under a company tractor – intersected with legal institutions beyond the courts. This book is often said to be the first to examine norm creation through the historical process of public lawmaking (Tomlins, 2000b [34 Law Soc'y Rev.]).

After Pearl Harbor, Hurst and his wife, Frances Wilson Hurst, moved to Washington, D.C. Hurst first worked for the general counsel of the Board of Economic Warfare and then joined the Navy, where his assignments included work on a highly publicized treason case, leading eventually to *The Law of Treason in the United States* (Hurst, 1971b).

Even before returning to the University of Wisconsin after World War II, Hurst began to write about the crucial link he perceived between legal history and 'opportunities to apply informed, humane reason to influence the course of events' (Soifer, 1992). The 'Wisconsin Idea' of enlightened political leadership had lasting appeal for Hurst, and he repeatedly rejected job offers to teach at other prestigious institutions. Although Hurst was extremely reluctant to travel from his Wisconsin base, he nonetheless was directly involved in launching the international Law and Society movement, as well as in pioneering a new approach to legal history that has had worldwide impact (Christopher Tomlins, 2000a). He taught

full time at Wisconsin until 1980 and continued to publish after he retired. Hurst died in Madison on 18 June 1997.

Hurst's Scholarship

Hurst's scholarly career repeatedly underscored a core idea. In 1971, he summarized the enormous project he had undertaken: "A realistic history of law in the United States will be a social history of law, taking law as man-made, and as the product of both deliberation and drift, but not of any immanent superior order of reality" (Hurst, 1971a).

Hurst sought to describe and analyze how most people responded to a central problem. That basic issue, according to Hurst, requires consideration of 'whether men will be able to use the power of the politically organized community to secure the basic conditions of a decent life for the individual, without thereby destroying the very values they are trying to realize' (Soifer, 1992).

Throughout his decades of scholarship and teaching, Hurst sought to develop a new integration of the social science ideas of his era with careful historical consideration of the largely unexamined mass of law as it functioned on the ground, far removed from the doctrines promulgated by selected appellate judges that dominated – and still dominate – legal education in the United States. His ultimate goal was to address the needs of society by using law in all its forms. Lawyers thus were to be trained not only to be 'officers of the court,' but also to be 'officers of the state.' In particular, Hurst concentrated on tracking what he termed 'the expansion of middle-class energy.' Legendary for his diligence and prodigious scholarly output, Hurst also spent a great deal of time encouraging younger generations of legal historians. The correspondence that Hurst wrote to those who sent him their drafts and articles was noteworthy for the insightful and detailed feedback he provided – which he typed himself, replete with typos – as well as for his quiet, heartfelt encouragement.

Robert Gordon described the great reach of Hurst's innovative academic project as follows:

> After expanding the relevant record beyond prior appellate cases and their facts to all prior legal acts and the social influences on them, and the pending proceedings to the overall task of designing workable legal-regulatory arrangements for the present age, Hurst wrote his books as background briefs for present-day lawmakers.
>
> Gordon, 1975

To Hurst, social patterns mattered greatly. But he perceived that generalized thoughtlessness and a strong tendency to accept inertia and drift often served to counterbalance, or even to disable, other strong, competing commitments.

Through his prodigious output of scholarship on markets, legislation, monetary policy, and administrative actions large and small, Hurst pointedly emphasized the frequent unthinking clash between core values in the United States. He seemed to delight in clearly describing basic sobering paradoxes. For example, Hurst observed: "Individuals realize their humanity only in society, but they realize their individuality only in self-awareness, which consists in some sense of separateness." Moreover, he noted that such tensions afford protective coloration for 'shrewd men' who 'warp individualistic symbols of the constitutional ideal to sanction unchecked organized power' (Soifer, 1992).

As Hurst challenged traditional legal distinctions between public and private activity, he pushed himself and those who followed him to develop both extensive local data and expansive theories to capture and explain overarching patterns. In *The Growth of American Law* (Hurst, 1950), Hurst argued that 'law has been more the creature than the creator of events.' This famous book emphasized the impact of physical, technological, and social facts on nineteenth-century law and paid particular attention to the often inglorious role of the legal profession. Some have criticized Hurst for being too much a functionalist, and for inadequately attending to issues of power. Yet Hurst's 946-page *Law and Economic Growth: The Legal History of the Lumber Industry in Wisconsin, 1836–1915* (Hurst, 1964) highlighted the failures of laissez-faire. It also extensively documented Wisconsin's broad and detailed state regulation of a single industry during a period generally thought to have been at or near the apex of free-market ideology.

Hurst's Impact

William Novak asserted in 2000 that Hurst must surely rank as 'a broad-gauged socio-legal thinker of the first order, writing in the tradition of Tocqueville, Weber, Holmes, and Pound' (Novak, 2000). Hurst was original in his emphasis on place and time, particularly through his focus on his native Midwest. He was also innovative through his unusual illustration of the difficulty in discerning any clear patterns of progress in legal developments in the United States. Indeed, Hurst concentrated on exploring the intricate network of constraints – some perceived, some never understood, some formally legal, some not legal at all – that repeatedly confined and constrained the freedom of everyone.

In Hurst's view, Americans competed fervently, if often blindly, to manipulate whatever system they found in place in their particular context. He generally found it necessary to bemoan the power of deep habits that often produced irrational development and substantial depredations over time. Yet, Hurst also provided crisp accounts of the constitutional impulse among Pike Creek squatters, for example, as well as broad studies of such issues as the fierce, largely irrational conflict over gold and silver currency in the late nineteenth century.

Hurst sometimes has been inaccurately caricatured as part of the celebratory framework of some forms of 'consensus history.' Yet, the very broad-gauged quality of his work (an ongoing quest, in Novak's words, "to try to twist the tail of the cosmos") emphasized the mainstream at the cost of excluding, or at least understating, the importance of minorities and dissenting viewpoints throughout American legal history (Novak, 2000). Hurst's faith in fact-gathering led him to produce not merely a new way of looking at law but also an extended historical critique of what he called 'bastard pragmatism' – the propensity of people throughout United States history to

allow themselves to be dominated by the short term and the bottom line (Hartog, 1994).

Through his career, Hurst emphasized the difficult, if not impossible, goal of increasing both public and private accountability. In *Law and the Conditions of Freedom* (Hurst, 1956), he noted a clear historic preference among Americans for 'the promise of the future over commitments to the past, but also for the ambitions of the present over the claims of the future.' To Hurst, facts were crucial. Only through facts could a doubting optimist, such as Hurst himself, imagine enlightened leaders actually enhancing the general pursuit of 'lives of good conscience and fulfillment.' He maintained a broad view of the appropriate role for government.

If Hurst sometimes seemed unabashed in adopting what Daniel Ernst called 'a presentist approach to the past,' he remained first and foremost an innovative, exceptionally influential historian (Ernst, 2000).

There continues to be a considerable amount of scholarship published to discuss and honor Hurst, and there have been numerous symposia considering his work. After Hurst's death in 1997, the Law and Society Association established the James Willard Hurst Prize in legal history and, in 2001, the American Society for Legal History and the Institute for Legal Studies at the University of Wisconsin Law School created the Hurst Summer Institute in Legal History to assist and encourage legal historians early in their careers. The unusual number and breadth of symposia dedicated to Hurst only begin to suggest how significantly Hurst's emphasis on the impact of markets, legislation, monetary policy, social habits, and administrative actions transcended earlier boundaries. Through his enormous output of scholarship, his legendary generosity in giving scholarly assistance to others, and his noteworthy teaching, Willard Hurst changed the way the legal history of the United States is written and taught. By now, as Lawrence Friedman put it, "You're either a Hurstian or a reviser of Hurst" (Margolick, 1990).

Although Hurst has often been criticized for not considering groups that have been subordinated within the legal system, this retrospective critique does not negate the major importance and continuing relevance of Hurst's work. Hurst not only redefined an entire academic field, but he did much to expand the borders of legal history to other disciplines. The framework he applied in creating the first comprehensive overview of law in modern America has continued to open doors and to refresh legal history. Hurst's career challenges his successors to consider carefully the intricate, crucial, often paradoxical intertwining of legal ideas and social realities within the many realms in which people actually live.

Abstract

Edmund Husserl (1859–1938) was one of the most influential philosophers of the twentieth century. Inventor of the 'phenomenological method' for the analysis of physical and mental phenomena, with 'intentionality' at its center, and initiator of the 'phenomenological' movement of contemporary human sciences, he became the great critic of naive 'naturalism' in philosophy and psychology ('psychologism'), and of what he regarded as the loss of orientation, certainty, and thereby of credibility of modern science. His appeal for 'going back to the things themselves,' and for overcoming the crisis of modern science by a foundation of all science and philosophy in a clearly understood 'life-world' (*Lebenswelt*) inspired the work of a great number of philosophers, including Gadamer, Heidegger, Ingarden, Levinas, Merleau-Ponty, Ricoeur, and Sartre, as well as social scientists such as Buytendijk, Kurt Lewin, Luckmann, and Alfred Schütz. Husserl's impact on the social sciences was mainly indirect, through (1) revealing the deficiencies of a merely naturalistic approach in science, (2) supplying very detailed methods for the description of phenomena, relations and situations, and (3) stimulating applications of the phenomenological method in many areas of social science, e.g., in sociology as brought into effect by Schütz.

Life and Academic Career

Edmund Gustav Albrecht Husserl was born in Prossnitz, Moravia, on 8 April 1859. He studied mathematics, physics, astronomy, and philosophy at the universities of Leipzig (1876–78), Berlin (1878–81), and Vienna (1881–82), where he obtained his PhD degree in mathematics with Leo Königsberger in 1883. After a short period as assistant to the mathematician Karl Weierstrass in Berlin, and a year of military service, Husserl continued his philosophical studies with Franz Brentano in Vienna from 1884 to 1886, and with Carl Stumpf in Halle between 1886 and 1887, where he qualified as lecturer in 1887 with a postdoctoral thesis entitled 'Ueber den Begriff der Zahl. Psychologische Analysen' ('On the Concept of Number. Psychological Analyses').

Husserl became a professor in 1894, and moved to Göttingen in 1901. In 1916, he accepted a call to Freiburg to succeed Heinrich Rickert in the chair of philosophy there. Husserl retired in 1929. After the seizure of power in Germany by the National Socialists in 1933, his status of emeritus professor was suspended because of his Jewish descent, and, after a short reinstatement, definitively revoked in 1936 after the Nuremberg race laws. Husserl died in Freiburg on 27 April 1938.

Writings, Subjects, Approaches, and Contexts

Husserl's significance for philosophy, which is certainly greater than that for the social and behavioral sciences, rests on his establishment of a new way of dealing with philosophical problems, which he called 'phenomenology,' turning this expression into a 'technical' term by giving it a clearer delimitation and a weightier role than it had enjoyed with earlier philosophers such as Lambert or Hegel. The methods and content of Husserl's phenomenology, however, changed considerably during their development, which may be summarized in terms of three 'turns' of direction and aims: (1) the turn from early foundational work to antipsychologism, (2) the shift from descriptive to 'constitutive' phenomenology, and (3) coping with the 'crisis' of modern science by a new focus on the life-world.

From Early Foundational Work to Antipsychologism

In *Philosophie der Arithmetik* (*Philosophy of Arithmetic*, 1891, Husserl, 1950: Vol. XII, pp. 1–283), Husserl made an attempt at a descriptive-psychological foundation of arithmetic, presumably having in mind an extension of Weierstrass's program of basing the vast number of mathematical concepts on a small number of fundamental ones, by providing an even deeper foundation for the latter by grounding them in the psychical acts underlying the mathematician's work. In the course of these investigations, Husserl introduced (independently of C. von Ehrenfels, who is normally credited with this discovery) 'gestalt qualities,' which he treated under the name *figurale Momente*.

Less successful (with hindsight) was Husserl's criticism of G. Frege's definition of number. It invoked an objective but sharp countercritique by Frege, which seems to have persuaded Husserl of the impossibility of taking the special science of psychology (which proceeds inductively, falling short of universally valid statements), as a foundation for mathematics or even for all special sciences ('psychologism'). Therefore, in *Logische Untersuchungen* (1901), aiming at a foundation of logic, which at that time was usually set up on a psychological basis, Husserl advocated a consequent antipsychologism, which influenced contemporary philosophy profoundly. This concept was extended in his work *Philosophie als strenge Wissenschaft* (*Philosophy as a Rigorous Science*) (Husserl, 1950: Vol. XXV, pp. 3–62) to a critique of historicism and (under the label of 'naturalism') scientism (1910–11).

The positive foundation of logic was to be laid by a new foundational discipline to which Husserl, oddly enough, gave the name 'descriptive psychology,' despite his claim that it differed from empirical psychology as well as from Brentano's descriptive classification of psychical (mental) phenomena; it was to be 'descriptive' in the sense of presenting the

immediately given mental facts without presuppositions (*voraussetzungslos*). According to this earliest form of phenomenology, that which is intended in a mental act (perception, judgment, idea, etc.) is transcendent to the act itself and given only in 'adumbrated' (*abgeschattet*) manner, through changing phenomena, and therefore inadequately. By contrast, everything immanent to the act is free of adumbration and can therefore be regarded as given in an absolutely adequate manner. Moreover, intuition of what is immanently given appears as free of structural complications like those attributed to judgment in contradistinction to sensation. The contents of the sphere of immediate experience (*Erlebnisse*) are beyond every doubt; with 'intentionality' at its center, it is the secure ground of a foundational discipline, which is capable of justifying statements about essences (*Wesen*) and their relations, by a method, which Husserl first called 'eidetics,' but later called 'intuition of essences' (*Wesensschau*).

Particular relevance to a philosophy of the sciences may be claimed for Husserl's remarks on 'pure logic.' Pure logic is an a priori theory of science dealing with two kinds of fundamental categories: categories of meaning (concept, proposition, truth, inference, etc.) on the one hand, and categories of objects (object, state of affairs, connection, number, etc.) on the other. Husserl takes the unity of the propositions of a science (or a discipline) to consist in the unity of its explanatory principles, and finds his next task in the uncovering of the conditions of the very possibility of theories. The route is to proceed from preliminary studies, e.g., a 'purely logical grammar' investigating the components and connections of propositions, via the statement of laws obtaining between such categories, to an a priori 'theory of possible theory forms.' These investigations, continued only in *Formale und transzendentale Logik* (*Formal and Transcendental Logic*, 1929) and in *Erfahrung und Urteil* (Husserl, 1939), share a methodical aim: the "fixation of unambiguous, sharply distinct verbal meanings" (Husserl, 1901: Vol. I, p. 244; Husserl, 1939 (English translation 1973): Vol. I, p. 238).

This search for 'verbal meanings' is also one of the foremost goals of contemporary methodical philosophy and philosophy of science. Husserl, however, did not approach the joint methodical aim by actually constructing a language of science, but recommended an 'intuitive presentation (*Vergegenwärtigung*) of essence in adequate ideation,' obviously conceived as independent of and antecedent to any linguistic construction. The ideation to be performed is not an idealization (as in geometry), but pure description, aiming at the elevation of that which is inexact and essentially vague to something typical, a 'type.' By setting out in this way, phenomenology increasingly moved away from the other methodical currents of modern philosophy and came closer to the philosophy of life (*Lebensphilosophie*), from which, however, Husserl differs sharply methodically by ascribing a foundational value to experience, after its precise rendering as 'pure experience' (*reines Erlebnis*) in which meaning, anterior to everything real, is believed to constitute itself (philosophical intuitionism).

The Step from Descriptive to 'Constitutive' Phenomenology

Object and method of phenomenology were extended and partly revised in *Ideen zu einer reinen Phänomenologie und phänomenologischen Philosophie* (Husserl, 1913), and pure logic was also characterized in a new way. In Husserl (1901), the predicate 'ontological' had been restricted (diverging from tradition) to sciences such as geography, astronomy, and anatomy, which deal with concrete objects, and not with abstract objects (like the theoretical or nomological sciences). Now, the old term 'ontology' is taken up again in a new sense. Husserl takes being to be subdivided into highest kinds or 'regions,' so the sciences, which deal with them yield 'regional ontologies.' Above these (material) ontologies we find the formal sciences, mathematics and logic, which are aimed at 'form essences' (*Formwesen*) and give rise to a *mathesis universalis*. Treating the 'empty forms of region' as such, they comprise the forms of all possible material ontologies, and are nothing else but a 'formal ontology.'

In *Formale und transzendentale Logik*, formal logic was subdivided into (1) a pure doctrine of forms of meaning, or logical grammar, (2) the logic of consequence, or logic of noncontradiction, and (3) the logic of truth. The purely formal ontology was characterized more clearly as the logic of objects by severing it from the 'apophantic' logic of judgment, while the nomological sciences are deductive, formal–analytic sciences describing 'definite manifolds.' Fundamentally, new is Husserl's assessment of ontology as a naive–dogmatic discipline that is turned into a science only by its founding on a 'transcendental logic.' The term 'transcendental,' as explained in 1936, refers to "the motif of inquiring back into the ultimate source of all the formations of knowledge, the motif of the knower's reflecting upon himself and his knowing life" (Husserl, 1954: p. 100). Husserl's reflective 'pure consciousness' of 1913 is now determined further by its function as the 'transcendental ego,' having everything as its object, while never becoming an object itself, and granting access only through 'eidetic intuition.'

The absolute sphere, which is the foundation of ontology and may be distinguished from the ontological sphere as 'semasiological' (R. Zocher), is the object of a 'critical' transcendental philosophy, which Husserl can only conceive of as a fully developed phenomenology. It makes use of the grasping of essences as a tool for analyses, which approach the problem of foundation not as a methodological task, but as a problem of constitution in the classical sense: in this sphere, according to Husserl, valid statements may be obtained only by a sequence of increasingly radical reduction steps, each of which is to consist in a certain 'abstention' (*epoché*). The first two steps, i.e., 'phenomenological reduction,' leading to the phenomena, and 'eidetic reduction,' leading to the essential structure of consciousness, carry us on to the transcendental sphere. Access to it, however, is only given by 'transcendental reduction,' which is the 'absolutely universal reduction,' opening up the transcendental subjectivity, which constitutes the meaning of the world and its contents, and thereby all objecthood.

The Crisis of European Science and the Life-World

The period between World War I and the seizure of power by National Socialism in Germany abounds with diagnoses of crises, from the foundational crises in most sciences (claimed for psychology, sociology, economics, etc., following the

foundational crisis of classical mathematics so dramatically exposed by H. Weyl in the 1920s) to a general crisis of the times, of intellectual and moral orientation, and of European ('rational') culture generally.

Husserl gave much thought to this phenomenon and made out a growing loss of confidence in the sciences hitherto regarded as the firm foundation of Europe's rational culture. He analyzed this situation comprehensively in an article *Die Krisis der europäischen Wissenschaften und die transzendentale Phänomenologie* published in 1936 in a new and little-known Serbian journal and later forming the first two parts of the monograph bearing the same title (Husserl, 1954). The sciences, it seemed to him, while 'functioning' as well as ever technically, had lost sight of their origin as well as of their aims, and thereby lost their former role and status as a guide and a standard of reliable knowledge and moral responsibility. Husserl hoped for a renewal by recognition of the fact that all scientific knowledge and activity is grounded in and grows out of everyday life. This is a realm usually not reflected upon but capable of thorough analysis as our 'life-world,' the domain not only of the physically 'given,' but primarily of our social life. Our immediate experience is not that of objects given to our consciousness, but that of situations in which we find ourselves with other people, in social groups and institutions, participating in common meaningful action, handling (linguistic and other) symbols, and approaching with understanding even "the great symbolic systems such as language, myth, religion, art, etc.; all of which are essential elements of the *Lebenswelt* and therewith of highest interest to the social sciences" (Schütz, 1959: p. 96). The phenomenological analysis of these largely 'prepredicative' constituents of the life-world was envisaged by Husserl in the *Crisis* treatise and begun in his late- and posthumously published work *Erfahrung und Urteil* (1939), where he has recourse to the life-world and to the primacy of praxis over mere contemplation. But in front of them, he places the 'prepredicative' evidence of perception and of judgment based on perception, and thereby once more a prelinguistic foundational domain. The new approach remained to be developed by others.

Contexts of Discussion and of Influence

Notwithstanding the fact that "Husserl literally 'thought through his pen'" (Embree et al., 1997: p. 327), entrusting an incredibly large part of his ideas to shorthand memos that remained unpublished during his lifetime (and part of them until now), his thinking did not develop monologically, without context. During Husserl's student years, the careful study of Descartes, Leibniz, the British empiricists and Brentano was recommended to him by T. Masaryk (today less famous for his *Versuch einer concreten Logik* of 1887 than for his later career as the first president of Czechoslovakia), and Husserl himself testifies to the influence of William James's *Principles of Psychology* of 1890 on the shaping of his phenomenological thought. Having acquired some fame as a creative philosopher, Husserl corresponded with many experts in science and philosophy, and discussed his ideas at invited lectures at other German universities, and abroad in Vienna, Prague, Paris, Amsterdam, London, and elsewhere – events certainly prepared by the translation of the *Logische Untersuchungen* and the *Ideen* into several foreign languages.

The beginning of the 'phenomenological movement' may be seen in the exchange of ideas with students and collaborators of T. Lipps in Munich, who learned about Husserl's investigations through their fellow student J. Daubert after he met Husserl in Göttingen in 1902. In spite of having nothing in print, Daubert had considerable influence on the 'Munich phenomenologists' (among them M. Geiger, A. Pfänder, and A. Reinach), some of whom (like H. Conrad-Martius, A. Koyré, and E. Stein, later one of Husserl's private assistants) came to Göttingen to work with Husserl. They became the leading members of the 'Göttinger philosophische Gesellschaft' and main authors of the *Jahrbuch für Philosophie und phänomenologische Forschung*, founded in 1913, which published some of the great contributions (phenomenological and other) to contemporary philosophy, such as Husserl's *Ideen* in 1913, M. Scheler's *Der Formalismus in der Ethik und die materiale Wertethik* (*Formalism in Ethics and the Material Ethics of Value*) in 1913–16, and M. Heidegger's *Sein und Zeit* and O. Becker's *Mathematische Existenz* (*Mathematical Existence*), both in 1927. After its discontinuation in 1930, the publications' goals and role were taken up by the American journal *Philosophy and Phenomenological Research*, founded in 1940.

In Husserl's most active period, private assistants helped organize his literary production, defended his positions (e.g., E. Fink against neo-Kantian critics), and prepared lectures and notes for publication (e.g., the *Zur Phänomenologie des inneren Zeitbewußtseins*, prepared by E. Stein and edited by M. Heidegger in 1928, and, posthumously in 1939, *Erfahrung und Urteil* by L. Landgrebe). In 1940, H.L. Van Breda saved most of Husserl's *Nachlass* (including 40 000 pages of manuscripts, Husserl's private library and much of his correspondence), which today forms the core of the Husserl Archives at the Catholic University at Louvain, Belgium. Philosophical and related work in the phenomenological spirit is, beyond this, upheld by 'phenomenological societies' in several countries.

Impact on the Social and Behavioral Sciences

Husserl's own writings did not take up any topics directly relevant to the social and behavioral sciences and therefore had little influence on them during his lifetime. Yet, they greatly stimulated interest in the phenomenological method in other authors, who explored its applicability and fruitfulness within the social sciences, broadening and strengthening the phenomenological movement. Whereas the investigations of A. Reinach into the a priori foundations of civil law, and of M. Scheler into the origins of cultural development, are contributions to the philosophy of the social sciences rather than to social sciences proper, the potentiality of a phenomenological approach was recognized early in the psychology of personality (especially in the psychology of the subconscious and in psychiatry), and in experimental psychology, where it opened up new vistas for social psychology and the psychology of perception (D. Katz, A. Metzger, M. Wertheimer): the development of gestalt psychology (W. Köhler, K. Koffka) and of K. Lewin's field theory are unthinkable without the impact of Husserl's phenomenology (see also MacLeod, 1947). In the

field of sociology, the *formal sociology* (or sociological formalism) of A. Vierkandt and A. Gurwitsch have drawn explicitly on phenomenological ideas, and more recently, sociological systems theory, social constructionism and ethnomethodology have been clearly influenced by phenomenological thought (P. Berger, H. Garfinkel, E. Goffman, T. Luckmann, Niklas Luhmann, I. Srubar).

According to A. Schütz, "Husserl's signal contribution to the social sciences consists … in the wealth of his analyses pertinent to problems of the *Lebenswelt* and designed to be developed into a philosophical anthropology" (Schütz, 1959: p. 97). This development was brought about by Schütz himself, who met Husserl personally only in 1932, after publication of his own pioneering work *Der sinnhafte Aufbau der sozialen Welt* (*The Phenomenology of the Social World*, 1972), but established close intellectual contacts for the six remaining years of Husserl's life. Schütz became the towering figure of phenomenological sociology, and it is due to the considerable impact of his work that Husserl's phenomenology, beyond its historical merit of exhibiting the limits of naturalistic and atomistic thinking, has gained a lasting influence on the social and behavioral sciences of today.

Hutterite Demography

Douglas L Anderton, University of South Carolina, Columbia, SC, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Hutterites, a pronatalist religious sect that showed no evidence of intentional fertility limitation prior to 1950, have been widely used as a standard for high, or even 'natural,' fertility. A common and communal lifestyle among Hutterites gives further reason to expect less sociodemographic variation in fertility than many high-fertility populations and enhances their value as a historical fertility standard. The early Hutterite population has been the most commonly used age-specific fertility pattern, as a standard representing natural fertility, in a wide variety of demographic indices, simulations, and models. In turn, methods incorporating the Hutterite fertility standard have facilitated the study of departures from uncontrolled fertility, infecundability, and other biological aspects of fertility.

The unique demography of the Hutterites – a contemporary Mennonite sect of Germanic origin who lives in the Great Plains of the United States and Canada – has played an important role in the development of demographic theory and methods. Prior to 1950, they appear to have practiced no birth control for religious reasons and their high fertility levels give reason to believe they did not intentionally control their fertility (Eaton and Mayer, 1953). Their communally shared lifestyle, including the sharing of material resources, is also presumed to limit social or cultural variations in Hutterite fertility (Larsen and Vaupel, 1993). Because of their uniformly high and apparently uncontrolled fertility, studies of the patterns and determinants of fertility among the Hutterites have helped to shape our theoretical expectations for populations that do not make any conscious efforts to limit childbearing. And, as a result, the Hutterites have also been widely used in demographic methods as a fertility, and biological infertility, standard to which other populations are compared.

Hutterite Fertility

Many different estimates of fertility and fertility determinants among the Hutterites have been published in different studies (see Larsen and Vaupel, 1993). All of these studies agree, however, that Hutterite fertility is exceptionally high. Eaton and Mayer (1953) reported a median completed family size of 10.4 children among married women over the age of 45 in 1950. Recalculations using the data published by Eaton and Mayer report a lower completed family size with a median of 9.4 children, and a mean of 8.97 among the same women (Lang and Göhlen, 1985). These estimates are consistent with the modal completed family size of 10 children, and the maximum of 15 children, reported for the Hutterite sample analyzed by Larsen and Vaupel (1993). Even in this very high-fertility population, however, fecundability and the probability of conception decline substantially with age. The monthly probability of conception is estimated to decline by about two-thirds between ages 20 and 35 (Larsen and Vaupel, 1993), likely reflecting age-related influences such as higher probabilities of fetal loss, lower coital frequency, longer postpartum amenorrhea, etc., among older age women. Nonetheless, the age-specific influences on Hutterite fertility resulting in a decline of fecundability across ages appear to be largely biological in nature. Compared with other populations, the Hutterite population has exceptionally high fertility levels and the age-related decline in fecundability offers no apparent evidence of intentional fertility limitation.

The Hutterites as a Natural Fertility Standard

Because of their doctrines and behavior, the Hutterites are presumed to represent a *natural fertility* population. That is, as Henri (1961) argued, their childbearing patterns reflect no efforts to limit fertility bound to the number of children already born, i.e., parity-*specific* fertility limitation. In fact, the Hutterites were one of the populations Henri (1961) used to define and illustrate the concept of natural fertility. He also ensured a special standing for the Hutterites as a high-fertility standard when he found that they had the highest age-specific fertility levels of 13 historical populations he studied, all of which appeared to be natural fertility populations.

The Hutterites as a 'Standard Natural Fertility Population' – Coale's 'I' Indices

Hutterite fertility levels and age-specific fertility patterns have been used as standards in some of the most widely used fertility measures of recent years. The Princeton European Fertility Project (Coale and Watkins, 1986) popularized the use of Coale's (1969) 'I' indices, which compare fertility in a population with that of the Hutterites through indirect standardization. Coale's index of overall fertility (I_f) compares the number of births to women in a population with the number of births these women would have had if they had experienced the same high age-specific fertility rates as married Hutterite women (i.e., 0.550 births per year among women aged 20–24, 0.502 to those aged 25–39, 0.447 to those aged 30–34, 0.406 to those aged 35–39, 0.222 to those aged 40–44, and 0.061 to those aged 45–59, see Henri, 1961). Coale's index of marital fertility (I_g) similarly compares births

to married women with the fertility they would have had if they had experienced the Hutterite age-specific marital fertility rates. And, Coale's index of illegitimate fertility (I_h) draws the same comparison for nonmarried women, again using Hutterite age-specific marital fertility rates as a standard. A final fourth index is intended to capture effects of the proportion married upon fertility (I_m) through comparing the fertility married women would have with that all women would have, if both experienced Hutterite age-specific marital fertility rates.

Age Patterns of Hutterite Fertility as a Standard – Coale and Trussell's '*M*' and '*m*' Indices

Coale and Trussell's (1978) more formal mathematical modeling of age-specific marital fertility control also incorporates the fertility pattern of the Hutterites and Henri's (1961) other natural fertility populations as a standard for comparison. Coale and Trussell used 10 of Henri's natural fertility populations, including the Hutterites, to specify a standard age-specific pattern for natural fertility (*see* Demographic Models). The Coale–Trussell model attempts to parameterize the differences in overall levels and age patterns of fertility from these natural fertility expectations in populations with varying levels of fertility control. The level of fertility is then captured by two parameters of the model, Coale and Trussell's '*M*' index of fertility levels and their '*m*' index indicating departures from a natural fertility age pattern (1978).

Hutterite Fertility Determinants in Micro- and Macrosimulations

Not surprisingly, demographic simulation models have also made use of Hutterite fertility standards. Ridley and Sheps' (1966) initial (i.e., Cohort A) microsimulation of fertility, for example, used values of fecundability and postpartum non-susceptibility, which were derived from the Hutterite population. Bongaarts' more recent (1976) macrosimulation of fertility also incorporated Henri's (1961) natural fertility estimates as standards for age-specific patterns of fecundity and infecundity associated with sterility. In these simulations, the Hutterite fertility standards are used to represent biological fertility parameters in the absence of known parity-specific fertility control.

Limitations of the Hutterite Fertility Standard

As the theoretical definition of natural fertility has been challenged, so have the measures of fertility control which have utilized the Hutterite fertility standard. Comparisons with a Hutterite standard population, such as Coale's I_g index, may reflect differences in fertility, which do not arise from parity-specific control (Santow, 1995). And, as in the case of Coale's '*M*' and '*m*' indices, such comparisons may also fail to capture the heterogeneity of fertility behavior in populations being compared with the natural fertility standards (Okun, 1994), including the possibility of fertility control, which is not closely tied to parity such as birth spacing. And, in the last half of the twentieth century, Hutterite fertility began to show evidence of fertility control (Peter, 1987; White, 2002). Thus, one limitation of the Hutterite standard is the fact that it represents a time and culture, which now belong to history and may diverge over time from a hypothetical contemporary natural fertility population.

Although comparative indices and methods face many of the same limitations as any indirect standardization, incorporating the Hutterites as a constant standard population for empirically based comparisons has, nonetheless, been of considerable advantage to demographers. Use of the Hutterite standard has allowed meaningful comparisons of fertility levels and patterns across widely different historical populations. The Hutterite standard has also provided indices with a clearly interpretable and unambiguous reference to an empirically observed high-fertility standard.

The Hutterites and Biodemography

Underlying their use as a high-fertility standard in many different methods, the Hutterites in and of themselves offer a unique opportunity for demographers to explore biological aspects of fertility and fecundity. An absence of any evident parity-specific fertility control, along with very high fertility levels, makes the Hutterite population as the one that may be used to study biological determinants of fertility without the confounding influence of fertility limiting behaviors. However, a troubling concern in the study of historical populations that lack widespread evidence of fertility control is the extent to which there may be many subgroups within the population with different fertility levels and patterns arising from different behavior and sociocultural circumstances. The Hutterites' communal lifestyle and uniformly high fertility give no reason to suspect wide differences in fecundability and fertility from social or cultural forces. And the uniformity of the population in many demographic behaviors (e.g., universal marriage and early ages at marriage, short durations of breast-feeding and early weaning, short birth intervals, absence of induced abortion, low levels of premarital conception, etc.) is likely to minimize many sources of variation in fertility compared with other populations. This relative homogeneity, or absence of subgroup variation, is especially important to the recent use (and assumptions) of event history methods to estimate the underlying biological patterns of fecundability among the Hutterites. This allows researchers estimating fecundability with Hutterite data to assume the underlying patterns and variations they discover arise from biological variations (see Larsen and Vaupel, 1993, for a review and example of such studies).

As further studies provide more refined estimates of Hutterite fertility and fecundity, these will likely continue to serve as empirically grounded standards for our demographic expectations in the absence of intentional fertility limitation. The theoretical importance of these expectations to demography is evident in the significant role, which studies of the Hutterites have had in shaping the concept of natural fertility and debates over the nature of fertility limitation. Their methodological import is clear in the wide variety of methods already grounded in the Hutterite fertility standard.

Hybridity

Nestor G Canclini, Autonomous Metropolitan University, Mexico and National System of Researchers, Mexico

Abstract

The term hybrid has been employed since ancient times to name processes of syncretism in migrations and colonization, but it has historically been more significant in biology. Since the end of the twentieth century, it has been widely used in social sciences and technology. The intensification of globalized interculturality in the arts and music, of intercontinental distribution of communication industries and of population displacements has led to an increase in studies on hybridity in the fields of anthropology, cultural, aesthetic and religious studies, and cultural politics. At times, this term takes priority over such notions as mestizaje, syncretism, creolization, and transculturation. Studies on hybridity open the way to gaining a deeper critical insight into the diversified development of societies, their mixing patterns, and the intercultural movements of hegemony and resistance.

'Hybridity,' originally a biological term, has been used by scholars in the social sciences, literary, artistic, and cultural studies to designate processes in which discrete social practices or structures, previously existing in separate form, are combined to generate new structures, objects, and practices.

Even if the study of hybridity processes has only been systematized during the last few decades, cultural mixing – or hybridization – has existed since the first exchanges among peoples, the first migrations, and wars of conquest. The Tower of Babel is a story of *mestizaje*. Plutarch used the term syncretism for political alliances. Pliny the Elder mentioned hybridization when referring to the migrants to Rome in his day. The historians of the Christian evangelization of Africa, Asia, and the Americas (G. Prius, S. Gruzinski) have recorded that converts did not abandon their traditional beliefs but reelaborated and fused them with those of the western missionaries.

The research into hybridity processes has become more extensive during the 1980s and 1990s, particularly in English and Spanish, whereas in other languages, such as French, the term coexists with similar concepts like *mestizaje* and syncretism, favored by French scholars. Some authors place these terms under 'hybridization,' thereby granting it the flexibility to include processes of intercultural confluence.

A study of various databases in July 2012 in order to compare references to hybridity in social sciences publications from 1990 to 2000 with those from 2000 to 2012 reveals a notable increase during the second period. Jstor in English brought up 1366 references for the first period and 2934 for the second. According to Scopus, articles on hybridity have risen from 94 to 730 during the respective periods. Whereas Google Scholar identifies 9290 references in English during the former period and 21 700 during the latter, its Spanish results show a decline from 1650 during the first period to 1400 during the second.

The Term Hybridization in Biology, Social Sciences, and Technologies

The use of hybridity in the humanities and the social sciences has been questioned due to the biological origin of the concept. Some point to the dangers of transferring the sterility commonly associated with this term to society and culture. Whereas this criticism is still found in recent studies, it is an extension of a nineteenth-century belief, when hybridization was looked upon with suspicion because it was believed to harm social development. However, this opinion has changed since 1870 with Mendel's theory of the enrichment produced by genetic crossbreeding and its examination during the twentieth century (Olby, 1984). In strict terms, biology, particularly botany, teems with fertile hybridizations that take advantage of cell characteristics of different plants to improve the growth, resistance, quality, and economic and nutritional value of food stuffs derived from these combinations (Callender, 1988). Hybridization of human DNA with bacteria to produce protein is also common; this is, in fact, the main means to generate insulin.

The biological background of the term does not explain its acceptance in the social sciences. Like other concepts imported from biology, such as *reproduction*, which had to be redeveloped in order to speak about social, economic, and cultural reproduction, the theoretical solidity and explanatory power of hybridity in social sciences depend upon the manner in which the term is relocated within the networks of specific social and cultural concepts.

On the one hand, hybridity is linked with more traditional notions of social thought that allude to the separation and mix among cultures and strata: race, ethnicity, *mestizaje*, miscegenation, syncretism, identity, multiculturalism, heterogeneity, creolization, transculturation, bricolage. On the other, the understanding of this term, its treatment and epistemological consistency depend upon the manner in which different authors link the concept with terms and theories, such as tradition, modernity, contradiction, globalization, postmodernity, and border studies.

Several disciplines have played a role in the sociocultural construction of hybridity. As a linguistic process, it was developed by Mikhail Bakhtin, among others, who used it to describe the coexistence of elite and popular languages in the same group, or even in a single speaker, and by Homi K. Bhabha, who defines hybridity as a metonym of presence and places it amidst power relations, noting differences between colonial and resistance hybridization, depending

on whether the linguistic and literary discourses serve the purposes of domination or subversion (Bhabha, 1994). Some historians of the Americas speak of hybridity to explain the interweaving of pre-Columbian imagery with the imagery of the Spanish colonizers and with that of later modernity cultures (Gruzinski, 1999).

From the end of the twentieth century, various disciplines and schools of cultural thought have adopted the concept of hybridity for creative processes in the visual arts and literature. It has become a descriptor of heterogeneous esthetic repertoires arising from the mixing of resources, such as tradition and modernity, artisanry and technology, local cultures and transnational iconographies (García Canclini, 1995; Papastergiadis, 2005). It is also useful for recognizing the increasingly important hybrid musical forms and genres, such as jazz, reggae and fusions of rock with Celtic music, salsa, tango, etc. Its reach even destabilizes biological orders and classifications, such as transexuality. Likewise, hybridity in education, so some suggest, makes children aware of multicultural creativity in order to steer them away from racist attitudes (Gallager-Geurtsen, 2009). This term is used, moreover, for automobiles that combine electric energy with internal combustion, gastronomy that fuses ethnic and national traditions and eclectic architectures, such as those that mix styles from different epochs within the same building, following the logic of postmodernism. Is there a danger that the elasticity of this concept so undermines its rigor that it eventually becomes banal? For this reason, it is worth bearing in mind the debates of those who reject the notion of hybridization and of those who compare it with other similar concepts.

Mestizaje, Syncretism, Transculturation, Creolization, and Hybridization

A number of historians and anthropologists have shown the decisive role of *mestizaje* in certain areas, such as the Mediterranean, since the classical period of Greece (Laplantine and Nouss, 1997). But the more intense – or researched – periods of interethnic and intercultural mixing occurred at the time of European expansion across the Americas.

Mestizaje became the prevailing process within the cultures of the so-called New World, because of the mixing of colonizers from Spain and Portugal, and, later, from Britain and France with the indigenous peoples and, subsequently, with African slaves. Nowadays, less than 10% of the population of Latin America is descended from indigenous peoples alone (this percentage decreases in the USA and Canada). Communities of European descent that have not mixed with indigenous peoples are also a minority. Thus, the makeup of all of the Americas requires the notion of *mestizaje*, both biologically, in terms of the production of phenotypes from genetic crossbreeding, and culturally, in terms of the fusion of European and indigenous American customs, beliefs, and modes of thought.

For a very long time, studies foregrounded the physiognomic and chromatic aspects of *mestizaje*. Skin color and physical features are still critical to the ideological construction of subordination and discrimination; however, in the social sciences and in more democratic political thought, *mestizaje* currently centers on the cultural dimension of the combination of identities. In anthropology, cultural studies, and cultural policy making, the issue is presented as devising ways to share multicultural life styles (Kymlicka, 1995).

Of the diverse crossings among cultures, fusions of religions have received the most attention. Syncretism is the specialists' term for this issue. European expansionism in Africa, Latin America, and Asia gave rise to multiple mixed forms: heterogeneous beliefs fused and new divinities emerged (the Virgin of Guadalupe in Mexico, the combination of African ancestors, indigenous figures, and Catholic saints in Brazilian Umbanda). Practically, every religion has fundamentalist tendencies that seek to defend pure forms, but the magnitude of migration and the transcontinental circulation of rituals and beliefs during the eighteenth and nineteenth centuries stressed these hybridizations and increased tolerance toward them to such a point that in countries such as Brazil, Cuba, Haiti, and the USA, it was frequent to find a double or triple religious affiliation. For example, a Catholic might participate in an African-American ritual or in a New Age ceremony. If we broaden the concept of syncretism to include affiliation to several belief systems as well as religion, the phenomenon grows remarkably, particularly among the many people who turn to indigenous or Asian medicine for certain ailments, to allopathic medicine for others, and even to Catholic or Pentecostal rituals. These syncretic practices are often combined with musical fusion and multicultural social organization systems, as is the case in Cuban *Santería*, Haitian Voodoo, and Brazilian *Candomblé*.

It was some of these phenomena that concerned the Cuban historian and anthropologist, Fernando Ortiz, when he proposed the term *transculturation* to designate "processes in which features are not mechanically aggregated, but give way to a new phenomenon, independent and original." Bronislav Malinowski's endorsement of that utterance in an introduction to Ortiz's book, and its future development by literary critics Angel Rama and Mary Louise Pratt in their studies of travel writing, are still appealing; particularly in literature and in Anglo-Saxon and Latin American cultural studies.

The word creolization has also been used to refer to intercultural combinations, especially in anthropology and linguistics. It designates, *sensu stricto*, the language and culture created by variations on a dominant language with other languages in the context of the slave trade. It includes the variations of French in the Americas and the Caribbean (Louisiana, Haiti, Guadeloupe, Martinique) and in the Indian Ocean (Reunion, Mauritius), or of Portuguese in Africa (Guinea, Cape Verde), in the Caribbean (Curacao) and Asia (India, Sri Lanka). But whereas it presents paradigmatic tensions between orality and writing, elite and popular sectors, center and periphery, in a diversity *continuum*, Hannerz suggests its usage could be extended to the transnational field to name "processes of cultural confluence" characterized "by power, prestige, and material resources inequality" (Hannerz, 1997). He is not the only author to draw attention to the inequality and discontinuity of hybridity processes, but by emphasizing the significance of examining the increasing movement between center and periphery and the asymmetries among markets, states, and educational levels he challenges

those who consider *mestizaje* to be, simply, intercultural homogenization and reconciliation (Hannerz, 1996).

Hybridization, Modernity, and Globalization

Hybridization

Whereas scholars often use the terms mentioned above almost as synonyms, *mestizaje* takes precedence in studies on the mixing of 'races' or ethnic groups, and syncretism refers to religious fusions or traditional symbolic movements. Besides the fact that *mestizo* has no English equivalent (some Anglophone scholars include the Spanish term in their studies), research carried out during the 1980s in Spanish, English, and occasionally in French and Portuguese adopted 'hybridity' to include diverse intercultural mixes, such as ethnic *mestizaje*, syncretism, in relation to beliefs, and other modern fusions of arts and crafts with industry, of elite culture with popular and traditional cultures and with the mass media (Bhabha, 1994; García Canclini, 1995; Bernd and de Grandis, 1995).

Modernity

Modernity, of which nation-states are an expression, has coherently organized – at times in reality, at others in appearance – the diversity of cultures. There are fewer than 200 nation-states which comprise more than 600 languages and some 5000 ethnic groups. These states have had, at once, to organize multiculturality by means of diverse policies and to facilitate communication among the ethnic groups and the different languages in each territory. Even in the cases in which a single language is imposed upon the 20, 50, or 100 communities in the nation, this common language adopts diverse modulations in the English- or Spanish-speaking country when it is combined or hybridized with the words, syntactic structures, and semantic references of the speakers of other tongues.

In the meantime, two other characteristics of modern development, transnational expansion of capitalism and of mass communication technologies, advance relationships and exchanges between local traditions and cultures of modernity. The crafts and celebrations of peasant groups travel, together with their producers, to cities and often to other countries, or they enter into contact with foreign tourists. Ethnic music, linked to specific rituals of a certain group, is not only recorded on CDs, movies, and videos to be distributed worldwide; it is also mixed with classical and contemporary music, with jazz, rock, salsa, and other local and regional kinds of music. This is how the *chicha*, a hybrid of Andean and Caribbean rhythms, was produced. Other examples include the jazzy reinterpretation of Mozart by the Afro-Cuban group Irakere, the recreation of English, Indian, and other music by the Beatles, Peter Gabriel, and many other musicians.

The strict borders established by nation-states have become blurred. Few cultures today are stable units with precise boundaries defining the settled area of the territory. But the multiple opportunities to hybridize imply neither indetermination nor unrestricted freedom. Hybridization occurs under specific historical and social conditions, in the midst of production and consumption systems that sometimes operate as constraints, as can be witnessed by the lives of many migrants. The city is an exemplary social entity that supports and conditions hybridity. The multilingual, multicultural megalopolises, for example, Paris in the nineteenth and the twentieth centuries, Vienna at the beginning of the twentieth century, London, Berlin, New York, Los Angeles, Buenos Aires, Sao Paulo, Mexico, and Hong Kong are studied as centers where hybridization kindles greater conflict and cultural creativity (Appadurai, 1996; Hannerz, 1996).

The wide range of processes of exchange and mixing involved in hybridization has led to the construction of typologies. Peter Burke's study is one of the most meticulous accounts of the diversity of meanings and inequalities. Supporting his proposal with cultural encounters from every continent, this historian distinguishes, firstly, intercultural *imitation* from *appropriation* and *reuse*; secondly, he mentions *borrowing* and, finally, his alternative: *bilateral transculturation*, *accommodation* and *negotiation*. It is, as he observes, the processes of accommodation and appropriation that provide the most diverse creativity and that require a reconsideration of *translation* in order to introduce cultural concepts to other linguistic communities, which may not have heard of them (Burke, 2009).

Globalization

Globalization stresses these trends of modernity by creating world markets of material goods and money, messages, and migrants (workers, tourists, exiles). These constant flows and interactions undermine borders, frontier posts, and the autonomy of local traditions. At the same time, they cultivate many more forms of hybridization than they did in the past, such as commercial, communicational, and consumer practices. What must be added to the modalities embodying hybridization – migration, travel, and educational integration policies introduced by nation-states – are the mixtures created by cultural industries. Industrialization encompasses not only the mass media (radio, movies, television, video), but also the industrial production for massive audiences of international exhibitions, touring folkloric groups, and globalized theme parks such as Disney's (Harvey, 1996).

However, the leading globalization analysts note that it not only integrates and generates *mestizajes* but also segregates, produces new inequalities, and stimulates controversial responses. Identity alliances emerge (Latins or Arabs in the USA or in Europe) as do regional organizations (the European Union, NAFTA, Mercosur) that aim, in part, to give different groups the strength to counteract the indiscriminate interaction of globalism (Beck, 2000). Some group members find the means in these alliances to resist both globalization and hybridization.

Homogeneity vs Differences?

Although most regional agreements between countries only regulate free trade, economic and financial globalization increases interdependence and reciprocal influences between cultural traditions and means of expression, formerly so distant from each other. The global movement of goods and messages stimulates creative practices and consumer habits in

western countries to include African or Asian objects, forms, and esthetics in their repertoire. Conversely, African and Asian countries are no longer the destination for a small number of missionaries, traders, anthropologists and adventurers, but for large numbers of material and symbolic objects produced in the West. This hemispheric interaction blurs the profiles that had, in former centuries, established sociocultural autonomy in each region. Contributing factors include not only the global circulation of capitals, material, and media goods but also the geographic expansion of migrations. Two examples illustrate this: many more Arabs and Koreans are now settling in western societies and Latin Americans are moving their point of reference from the United States of America and Europe to seek employment in Arab and Asian nations as well.

These concepts have also extended their horizon of application. The notion of diaspora, utilized historically to describe the dispersion of Jewish, Greek, and Armenian peoples, is now used, as Ien Ang observes, to analyze almost any group living outside its country of origin. The migrants' increased possibilities of communication with their original homeland through improved transport, the mass media, and digital networks means that they no longer see themselves as minorities within the host nations but as members of global diasporas; the 'overseas Chinese,' or the dispersal of the Chinese throughout the world, provides an eloquent example (Ang, 2003). Whereas these groups engage in processes of hybridization with their new surroundings, they reaffirm their customs, at the same time, as they are often in touch with their country of origin. Hybridization destabilizes identities, as it blurs the boundaries between the Chinese and the non-Chinese, Islamists, and westerners, but the new institutions that organize diaspora, such as the transboundary trade networks and web pages, create a form of transnational nationalism.

Recent globalization produces a more complex combination than in the past between homogenizing tendencies and affirmation of differences. Technological advances and the potential to have customers all over the world have engendered movements of homogenization, such as equalization, to use a musical term: electronic devices alter the timbre variations and local melodic features for the purpose of stylizing them and eliminating whatever might sound discordant to listeners from other cultures (de Carvalho, 1995). But readings that attempt to reconcile diversities reveal the covert inequalities in the production, circulation, and consumption of culture. An analysis of the strategies of commercial hybridization should locate them in what Ulf Hannerz calls the "political economy of culture inherent to the mestizo *continuum*"; that is, the uneven distribution of centers and peripheries, and even "the coexistence of various *continuums* instead of a single and exclusive *continuum*" (Hannerz, 1997: pp. 115–116). That the countries of the center pay more attention to underdeveloped countries, and that the migrants and Latin American messages are hybridized in the center (ethnic musical discs recorded in New York, Miami, Mexico, and Buenos Aires, and these cities converted, at the same time, by MTV into the capitals of Latin American rock) does not signify the abolition of center and periphery.

Unlike the conventional debates about the issue of homogeneity versus differences, the contemporary scene inspires a consideration of the zones of exchange, instead of choosing one or the other. The question is how to find a common denominator and how members of different cultures coexist, if they are only partly hybridized. Which settings foreground this reformulation of the problem most readily? Metropolises and cosmopolitan cities, ports and borders have been throughout history typical cases of intersections among hybrid cultures; they also sustain their differences and reinvent traditions, languages, gastronomy, and the arts. At the present time, the Internet has strengthened multicultural coexistence and created an increase in worldwide conflicts. As many authors write, we may experience intercultural tensions anywhere; any place can become a border.

Burke suggests that throughout history there have been four ways of responding to this situation: (1) *the imitation of the foreign models*, based upon admiration, tolerance, and in many other cases upon an all too harmonious vision of the exchanges between differences; (2) *resistance* to any external force perceived as an invasion, which has antecedents in the distant past, such as the prohibition of foreign books, studying abroad, when Philip II was on the throne in Spain (1559), or the Muslims' banning of the printing press until 1800, because it threatened the oral transmission of knowledge; (3) *cultural purification*, or a reaction against the acceptance of the foreign and a deconstruction of what has been borrowed and assimilated, that is, a dehybridization such as that which occurred during Nazism, the French response to the *défi americain* and the more recent measures taken by European countries requiring that immigrants observe the traditions and language of their adopted country; and (4) *cultural segregation*, which applies, for example, to some Asian groups who, finding it difficult to keep their entire territory uncontaminated, select areas to remain free from westernization or defend the indigenes as a source from which to regenerate communities within capitalism; it also applies to those such as the Japanese who lead a double life, by adhering to a foreign culture at work and turning to their own traditions during their spare time (Burke, 2009).

In sum, the increase in exchanges at this stage of globalization is not a one-way street. There are homogenizing tendencies that include diverse labor and consumer practices as compatible parts of the same mode of production. Contrary to the fear of the Americanization of the planet or the exclusive domination of the English language, several other languages, such as Chinese, Spanish, and Arabic are enjoying a period of expansion. Moreover, antiglobalization and deglobalization movements are strengthening local traditions, often acknowledging, nonetheless, that they are making productive use of appropriations from external sources.

Studies on '*structural hybridism*' (Nederveen Pieterse, 2000) of the contemporary world thus contribute to a social theory of nonunidirectional globalization, understood not as a homogenization process but as diversified development through the mixings and coexistence of cultural traditions that never quite fuse. It is worth recalling the unequal distribution of development and access to the processes of hybridization, because it depends on the position of each culture or group in power hierarchies. The combinatory faculties of producers and consumers are different in the movements of *endogenous hybridization*, or the local and

self-managing circuits, from those of coercive *heteronomous hybridization* that concentrate on appropriating characteristics from many cultures and making them circulate among a few transnational enterprises that produce messages and goods, administration, and editing of multicultural meaning.

Just as this occurs with the *spatial* distribution of hybridization strategies, so Brian Stross has described the differences of the '*hybridization cycles*.' He states that we pass, in historical terms, from more heterogenic to more homogeneous forms, and then again to other more heterogenic forms, depending on our ability to construct hegemony and establish a given state of intercultural combinations.

The Future

Beyond those naive conceptions of hybridization as processes of universal reconciliation, it is clear by now that the greatest interdependence between cultures creates, at once, multiple conflicts and rapprochement between symbolic and material practices. By no means is this the case only outside the homeland: we have frontier experiences, even in our place of birth.

Having passed from societies that impose restraints on multiculturality (each minority in its own quarter) to a more open and diffused interculturality, anthropologists and cultural analysts argue that we should focus on the zones of exchange, rather than on identity studies (ethnic and national). Do the concepts of hybridization, *mestizaje* and syncretism help us to organize conceptually those more complex processes of interaction? They do, so long as we do not expect a fixed meaning for these concepts and recognize the range of situations that might occur on the zones of exchange. Concepts are, as Mieke Bal writes, the sites of debate, where consciousness of differences and mixings is raised, and, subsequently, attempts to reach a reciprocal understanding are proposed. Agreeing doesn't mean agreeing on content, but agreeing on the basic rules of the game: if you use a concept at all, you use it in a particular way, so that you can meaningfully disagree on content (Bal, 2002).

Specialists in the fields of anthropology and cultural studies maintain that the evident relevance of hybridization requires changes to the methods normally used in the social sciences. It is no longer possible to analyze large units, that is, nations, states, transnational enterprises, without noticing their internal diversities and modulations, as often happens in disciplines that analyze at macro level, such as sociology and economics. Nor is it acceptable that anthropology, which has traditionally studied small communities, should continue solely to identify their homogeneity, thereby ignoring the heterogeneity and hybridization caused by the transnational goods and messages that intersect these communities. A commitment to a political negotiation of diversity and hybridizations requires a '*mestizo* way of thinking' (Laplantine and Nouss, 1997; Gruzinski, 1999).

Fundamentalisms are not the only opposition to religious syncretism and intercultural *mestizaje*. Many reject hybridization because it generates insecurities within cultures and conspires against their ethnocentric self-esteem. It also challenges trends in modern analytical thought accustomed to conceptual pairings: civilized–wild, national–foreign. This schematism ignores many ways in which culture is shared nowadays, such as someone who is Brazilian by nationality, Portuguese by tongue, Russian or Japanese by origin, and Catholic or a believer in an African-American religion.

In the future, hybrid thought will not work so much with radically different homogenous compact units as it will with intersections, transitions, and transactions; it will express less concern for identity than for heterogeneity and multiple senses of belonging. In order to gain a greater insight into the contemporary world, it is essential to study how cultures mix, what are the rhythms and modalities of this mixing, what they lose and gain in the process, which modes of coexistence they have chosen, and how they conduct their negotiations to sustain their differences. Moreover, we must understand hybridity and learn to be cosmopolitan 'multicultural gourmets,' who travel through diverse cultures and savor the differences, if we are to comprehend globalization and the ethnic and national crises in societies. In sum, if we are to comprehend society.

Abstract

From the standpoint of the social and behavioral sciences, hypertension has attracted a great deal of attention. It forms the backbone of the growing fields of health psychology and behavioral medicine. The evidence is supportive of the role and significance of psychosocial factors in the etiology, course, and treatment of hypertension. This knowledge has the potential for deepening our understanding of the mechanisms involved in hypertension, improving the effectiveness of both drug and non-drug treatment, and facilitating efforts for prevention. There is great need for further systematic research and especially for theoretical and empirical integration of psychosocial and biological knowledge of the disorder.

Hypertension is a complex disorder of physiological regulation determining increases in blood pressure that stay high over time. Leaving aside the less common cases of so-called secondary hypertension, the causes of which are well known (e.g., endocrine diseases, kidney diseases, drugs, and tumors), about 95% of cases of hypertension are likely to be the consequence of an interaction between many environmental and individual factors. US surveys indicate an age-adjusted prevalence of hypertension (>140/90 mmHg) of between 28 and 30% in adults aged 18 and over. Interest in the role of psychosocial factors in hypertension has a long history beginning with theories about social stress, affective processes, and individual behavioral dispositions in its etiology. Noteworthy are the early psychosomatic writings about the significance of anger expression and suppression for high blood pressure.

Direct and Indirect Evidence

Numerous studies provide evidence of a definite role for psychosocial factors in hypertension. Direct evidence is derived from cross-sectional studies of individuals with hypertension compared to control samples and longitudinal studies to determine what factors are associated with the development of hypertension. Indirect evidence comes primarily from studies of psychosocial factors affecting blood pressure in healthy individuals with or without various predisposing characteristics. Psychosocial factors are also relevant to the degree of adherence to medications, engagement in health-related behaviors affecting (buffering or increasing) risk for hypertension, and effectiveness of antihypertensive medications and of nondrug methods of managing hypertension based on psychosocial concepts and methods.

Blood Pressure Reactivity and Hypertension

Elevations in blood pressure can be elicited by many different stimuli and circumstances involving psychological and social factors. Examples are exposure to noxious, painful, threatening, or otherwise stressful stimuli and events, participation in demanding tasks requiring repeated behavioral and/or mental adjustments, continuous striving and active coping, frustration in achieving goals, mental effort especially in solving difficult problems, momentary moods and behaviors involving fear, anger, and other emotional states, inhibition or suppression of emotional states and reactions, conflicts about the expression of angry feelings or other negative emotions, and interpersonal and group conflict. Moreover, even blood pressure responses to simple physical efforts like postural change may be affected by psychosocial factors (Davydov et al., 2012). Social-cultural norms define what are appropriate and desired reactions and behaviors. The extent to which blood pressure is affected is determined by the balance between demands placed on the individual and on one's resources and ability to cope with the demands.

A common theme in the literature is that individual differences in cardiovascular reactivity (CVR) to various stimuli and events serve as a risk factor for hypertension and cardiovascular disorders in general (Carroll et al., 2012, 2011). Increased emotional reactions, sympathetic activity and associated hormonal and humoral changes, and the sensitivity of peripheral tissue are considered mechanisms of excessive CVR and pathways to established hypertension, where activation of the sympathetic nervous system seems to play a pivotal role (Gamboa et al., 2012; Lovallo, 2003; Singh et al., 2010). Most antihypertensive medications appear to regulate blood pressure by interfering with these mechanisms. A defect in baroreflex and vagus regulations may also contribute to hypertension (Davydov et al., 2010a, 2007; Lohmeier et al., 2009; Paton et al., 2005; Sartori et al., 2005; Thrasher, 2006).

Psychosocial factors are associated with higher casual or ambulatory levels of blood pressure, suggesting that the transformation from excessive reactivity to a chronic elevation may take place with repeated instances of blood pressure increases. Thus, in some samples of subjects, levels of blood pressure, especially during sleep, have been found to be positively associated with negative moods (e.g., angry, stressed) during the day and such personality traits as hostility and anxiety (Davydov et al., 2010a; Shapiro et al., 2001, 1997b). Physiological models have been developed to describe the cardiovascular dynamics underlying the transformation from

early heightened reactivity to later established high levels of blood pressure.

Hypertension may be related to a physiological mechanism of protection of positive mood with a resulting negative somatic outcome (high blood pressure) for the maintenance of positive subjective well-being in the face of aversive, threatening or unfriendly surroundings (Berendes et al., 2013; Davydov et al., 2012). For example, chronic pain and chronic negative mood may increase hypertension risk as a physiological compensation mechanism regulating arousal systems in persistent coping with negative challenges (Davydov et al., 2012; Drouin and McGrath, 2013; Olsen et al., 2013). This may explain associations found between negative mood and subsequent elevation in blood pressure and a proposal to use blood pressure reactivity to some challenges as an objective metric of individual capacity for mental resilience against chronic or occasional adversity (Davydov et al., 2012, 2010b).

Methodological and Conceptual Issues in Research on CVR

Debates continue about the evidence supporting the CVR hypothesis based on responses to laboratory stressors (Zanstra and Johnston, 2011). Most laboratory studies of CVR are limited in the range of cognitive, social, emotional, physical, and complex tasks studied. Inter-task CVR consistency is not high, indicating that no single task may be able to represent a CVR trait of the individual (Ottaviani et al., 2008). Individuals vary widely in their blood pressure responses to various circumstances. Variations in the kinds of individuals and methods chosen for study may result in different findings and conclusions. Laboratory settings may impose constraints on the participants so that they may not respond to challenges and threats with their preferred method of coping. And individuals vary in the degree to which their responses persist over time for any one provocation or generalize across provocations.

One alternative to laboratory procedures is to assess CVR in everyday settings using diaries and ambulatory blood pressure measures (Shapiro et al., 1993; Zanstra and Johnston, 2011). However, a problem of naturalistic studies is that each participant in a specific sample may be differentially exposed to daily life stressors during a selected sampling period. Averaging CVR evoked by different stressors has been proposed as a way to improve reliability of measures obtained under controlled laboratory conditions for evaluating CVR as a trait of the individual (Kamarck et al., 2000; Zanstra and Johnston, 2011).

The association between perceptions of stress and the blood pressure response to such stress may not be consistent because some individuals tend to intentionally or non-intentionally over- or under-report moods and emotional states while at the same time showing decreased or increased physiological reactivity to provocations or diminished or elevated blood pressure levels in general. These individuals either generally do not feel the reported emotions or wish to make a favorable impression on other people (Davydov et al., 2013). These characteristics have been labeled as 'defensiveness,' 'alexithymia,' or 'response style' (Shapiro et al., 1996). Individuals may learn to cope effectively with stress or keep their emotional responses under control. For example, experienced air traffic controllers or other professionals dealing with emergencies do not necessarily show elevated levels of blood pressure (Sega et al., 1998). By taking these various factors into account, further sense may be made out of the inconclusive findings and the soundness of the reactivity model.

The ability to predict the development of sustained high levels of blood pressure, established hypertension, and cardiac events may be improved by considering other psychological factors such as various personality traits and coping styles (anger/hostility, defensiveness, emotional suppression, denial, repression, anxiety, lack of control and helplessness, Type A and D personality, depression, pessimism) (Brydon et al., 2010; Einvik et al., 2011; Everson-Rose and Lewis, 2005; Gleiberman, 2007; Lévesque et al., 2010; Rutledge and Linden, 2003; Smith and MacKenzie, 2006). In the social domain, contributing factors are low socioeconomic status, social disintegration, and family disruption (poverty, high crime rates, high divorce rates), everyday hassles, occupational stress (job strain, job dissatisfaction, high job demands, little independence in one's work duties or latitude in the ability to make decisions), low levels of family and social support, social isolation, taxing responsibilities such as providing care to disabled family members, marital conflict, minority social status, ethnicity, and gender (Everson-Rose and Lewis, 2005; Kamarck et al., 2005; Lin et al., 2011). For example, in a large prospective study, after controlling for multiple confounding factors, greater reactivity to a mental stress task was associated with higher resting systolic blood pressure, more upward drift in resting systolic blood pressure, and hypertension 12-years later, providing some support for the reactivity hypothesis (Carroll et al., 2011).

Exploiting mediation and moderation analyses may help explain associations between psychosocial factors, CVR, and hypertension. For example, defensiveness was found to determine hypertension based on CVR (Rutledge and Linden, 2003). Anger and hostility do not necessarily have the same implications for men and women. An important missing link between CVR and subsequent established hypertension has been suggested by research on the degree to which individuals recover from reactions to stress and on rumination (Davydov et al., 2011; Ottaviani et al., 2011). In a laboratory study, it was shown that recovery after stress (recalling an experience 'that made you very angry') was much greater if the participant was distracted. Moreover, in a 24-h ambulatory recording, systolic blood pressure at times that the person was thinking about the anger experience was 20 mmHg higher compared to times without such rumination (Ottaviani et al., 2011). See Gerin et al. (2012) for an overview of this framework.

Biopsychosocial Models

The ability to predict whether repeated elicitations of increases in blood pressure will lead eventually to chronically elevated blood pressure and to cardiovascular disease is probably best improved when certain biological factors are included in the test models, such as obesity, physical activity, physical

conditioning, salt sensitivity, excitable autonomic nervous system, deficiencies in certain vitamins and minerals, intake of sodium and potassium, presence of other disorders such as diabetes, high glucose, insulin, or lipid levels, certain racial characteristics, and other genetic or constitutional predispositions such as family history of hypertension and cardiovascular disease (Lovallo, 2003; Singh et al., 2010). In a study of occupational stress in nurses, those nurses for whom both parents had hypertension and who were hostile, defensive, or anxious had elevated ambulatory blood pressure, which was highest during work days (Shapiro et al., 1996). A similar finding is reported by Vögele and Steptoe (1993) who found the highest CVR in adolescent boys who had a tendency to suppress anger expression and whose parents had high blood pressure, indicating a raised risk of future cardiovascular disease. Other psychosocial, life style, and habitual behavior patterns need to be considered as they are relevant to one's diet, activity level, and intake of caffeine, alcohol, and other substances. For example, certain personality traits like a high level of trait hostility may be associated with unhealthy health habits such as smoking, low levels of exercise, poor physical conditioning, poor nutrition, and increased number of social, family, and occupational stresses and conflicts. These associations are explained by a bidirectional model of person–environment interrelationships when stressful and other risk factors are considered as a combination of random and non-random events with the latter influenced by an individual's own reactivity phenotype (Davydov et al., 2012).

Diagnostic Issues

Psychological factors are relevant to the diagnosis of hypertension. Some patients may show elevations in blood pressure during a doctor's visit and evaluation ('white coat effect') but not at other times. This effect has been related to an alerting response to the examination or anxiety about one's health. In one study, trait hostility was found relevant to this effect. Those individuals who were highly hostile were consistently high in blood pressure during the examination and over the course of the day, whereas low hostile individuals were more likely to show elevated pressure only during the evaluation and not during the day (Jamner et al., 1993). Another study showed that if blood pressure was measured in alerting (standing) posture or at the start of doctor's visit higher blood pressure was related to lower level of depression, but if blood pressure was measured in the same subjects in a relaxing (lying) position or several minutes later during the same doctor's visit higher blood pressure was already related to higher level of depression (Davydov et al., 2012). By having the patient record blood pressure, concurrent behavioral activity, and self-reports at home and in everyday settings, useful information may be obtained on blood pressure responses and variability at different times and occasions that may guide decisions about treatment and increase the patient's adherence to medications or otherwise facilitate pressure reduction. Reliable wireless devices and 'cloud' communication technologies for building real-time and continuous ambulatory health tele-monitoring systems are now available for this purpose (Chan et al., 2012).

The Problem of Blood Pressure Variability

Blood pressure can be quite variable both in the short-term (minutes to hours) with a range from a small change to 60 mmHg over the course of meetings, public speaking, conflict, pain, waking from sleep, driving, posture, eating, smoking, etc. (usually of 10–15 mmHg for daytime and 5–10 mHg at night), and in the long-term (days to months) with a usual range of 10–20 mmHg over the course of chronic stress (e.g., work-related), visits to doctor, season, infection, shift work, menstrual cycle, depression episodes, stopping addictive habits, etc. (Rothwell, 2010). Short-term (e.g., within 24-h) and long-term (e.g., clinical and 24-h visit-to-visit) blood pressure variability were found to be only weakly correlated ($r < 0.2$) that challenges their equal prognostic value for cardiac events and cardiovascular mortality (Mancia et al., 2012). Moreover, in some cases enhanced blood pressure variability (e.g., high circadian difference of systolic blood pressure) was of a protective nature against follow-up cardiovascular mortality, but in others (e.g., high standard deviation of systolic blood pressure during the night) it was an independent predictor of cardiac events (Mancia, 2012).

These facts provided the impetus for the investigation of blood pressure in different settings with the control for their effects in various individual psychosocial and physical conditions for the correct diagnosis and the evaluation of drug effects (Davydov et al., 2012, 2010a). Thus, ambulatory blood pressure recording methods buttressed by information obtained from diaries of self-reports of moods and the situations encountered in everyday life offer many advantages, including a large number of blood pressure measurements under different conditions (work vs non-work or off days, sleep vs waking periods) and in a variety of repeatedly occurring situations, locations, and activities. Valuable data have been obtained from studies of special populations: paramedics, traffic control agents, secretaries, laboratory technicians, emergency dispatchers, nurses, bus drivers, and college students (Shapiro et al., 2002). The research is challenging because of the complexities and uncontrolled nature of the observations, but novel analytical tools show great promise (Davydov, 2013; Davydov et al., 2010a; Ottaviani et al., 2011).

Psychosocial Factors and Treatment of Hypertension

Psychosocial factors play a role in the treatment and management of hypertension. The response to antihypertensive drugs and to various behavioral methods may partly depend on psychosocial factors, although research is sparse on this topic and these factors are not usually considered in the choice of medications and methods used to treat patients. In one example, individuals with high levels of hostility were found less responsive to diuretics than non-hostile individuals, suggesting that the former might be more responsive to agents directly affecting the sympathetic nervous system (Pasic et al., 1994). Another study found that in emotionally stable people, training for avoiding negative stimuli perception was associated with elevated post-intervention blood pressure and higher blood pressure reactivity to stress (Higgins and Hughes, 2012). Ethnicity can affect the response to treatment

of hypertension (Kramer et al., 2004). Psychological factors influence degree of adherence to medications and may affect the degree to which side effects of medications occur and affect quality of life (Farrell et al., 2011).

A great deal of research has been devoted to the evaluation of nondrug treatments of hypertension derived from psychological and behavioral principles (Brannon and Feist, 2009). The methods include progressive relaxation, simple relaxation, biofeedback-guided relaxation, biofeedback training involving blood pressure, heart rate, and other cardiovascular measures, biofeedback training using measures associated with sympathetic nervous system functioning, cognitive-behavioral methods of facilitating coping with stress and dealing with anger ('stress management training'), hypnosis, and autogenic training. These procedures seem most suitable as alternatives in patients with mild hypertension, especially those who are free of significant cardiovascular disease risk factors (family history, high cholesterol level, smoking) and in other patients as a means of reducing the amount of medication needed for blood pressure control or completely eliminating the need for such medication (Guo et al., 2008). Reducing drug requirements may be of special value in dealing with undesired side effects of medications in some patients (Shapiro et al., 1997a). As yet there is no consensus about the effectiveness of these procedures, and major trials remain to be done (Dickinson et al., 2008). Other traditional methods such as yoga and meditation may be useful as a means of increasing awareness and control of mental and bodily functioning. Regular physical exercise can facilitate blood pressure reduction and improve the coronary circulation. Whether or not people exercise, avoid or take medications, or use herbal, homeopathic, or various nondrug methods is determined by many different psychological, social, and cultural factors (Glynn et al., 2010).

Hypnosis

Burkhard Peter, MEG-Stiftung, München, Germany

Abstract

Hypnosis is defined as the art of creating an alternative reality through imagination. The experience of evidence (illusion) and involuntariness (shift in agency) seems helpful, if not crucial, to the feeling of being hypnotized. Several variables are important to the quality of the hypnotic response, such as hypnotizability, hypnotic or trance state, hypnotic phenomena, hypnotic suggestions, context variables, motivation, and expectancy as well as relationship (hypnotic rapport). These factors are described, illustrated in its meaning and practical use, and substantiated by research results. Applications in medicine, dentistry, and psychotherapy are described, and relevant data supporting the efficacy of its use in these fields are provided. The role of Franz Anton Mesmer in historical reference as founder of modern hypnotism is challenged.

Hypnosis can be defined as the art of creating an alternative reality by imagination, which, ideally, should be experienced like a hallucination or illusion. In order to accomplish this, a person, with the help of hypnotic induction rituals, is 'put into' a hypnotic or 'trance' state, which is assumed to be a distinctive state different from normal experience. It is thought that being in a hypnotic trance makes it easier for the hypnotized person to use his/her hypnotizability to construe this alternative reality. Two experiences are helpful, if not crucial, for the feeling to be hypnotized: evidence (i.e., the subjective conviction of experiencing it 'as real'), and a shift in agency, from voluntariness to involuntariness (i.e., allowing for a kind of an 'alien control').

The more intense and real (evident) this alternative reality feels and the more it is experienced in form of hypnotic phenomena (i.e., hallucinations, illusions, and involuntary responses), the more likely normal reality is dismissed or dissociated, partially or as a whole, during the time of the trance state; and the more likely therapeutic relevant features of this alternative reality will be eventually implemented in everyday life. In that way, hypnotized patients can better tolerate aversive medical procedures, or, in the course of a hypnotherapy, can change their feelings, cognitions, and behavior.

Usually, the hypnotic trance is induced, and hypnotic phenomena are suggested by another person (heterohypnosis). However, they can also be self-induced (self-hypnosis). Several variables, which are more or less interconnected, play a role in the quality of the hypnotic response: the amount of hypnotic suggestibility or hypnotizability, the presence of a trance state and its depth, the kind of hypnotic phenomenon that is intended, the way in which suggestions aiming at a specific hypnotic phenomenon are presented, and the variables related to the context in which suggestions are presented. Motivation and expectancies are important too, as well as variables pertaining to the relationship between the person who gets hypnotized and the particular hypnotist or hypnotherapist in addition to his or her hypnotic skills.

Hypnotizability

The expressions hypnotizability, hypnotic susceptibility, hypnotic responsiveness, or hypnotic suggestibility are used interchangeably when the measurement of suggestibility is preceded by a formal hypnotic induction procedure. If there is no preceding hypnotic induction, terms like nonhypnotic, imaginative, or waking suggestibility are used. Hypnotic and nonhypnotic suggestibility are highly correlated. To assess hypnotizability, subjects or patients are presented with various suggestions that are intended to elicit certain hypnotic phenomena. The amount of hypnotizability is measured by the number of suggestions that are passed successfully. Similar to other personality traits, hypnotizability is normally distributed, with approximately 20% being high hypnotizables, 60% medium hypnotizables, and 20% low hypnotizables – depending on the choice of cutoff values (e.g., Peter et al., 2014).

Because correlations are unstable, the amount of an individual's hypnotizability cannot be reliably predicted from other personality traits; it can only be measured with hypnotizability scales. In recent years, a number of studies support the assumption that there may be two distinctive groups of high hypnotizables: individuals who like to be involved in hypnosis ('hypnosis prone'), that is, the classical 'fantasizers' with high imaginative abilities ('fantasy proneness'), and individuals who are highly dissociative and probably vulnerable to psychopathology (Peter et al., 2014). Twin studies and longitudinal studies point to the heritability of hypnotizability, as well as recent results from genetics: hypnotizability has been associated with genetic polymorphism in catechol-*O*-methyltransferase, an enzyme that is involved in dopaminergic metabolism. This led to the conclusion that high hypnotizables supposedly show greater frontal lobe dopamine-mediated flexibility than low hypnotizables (Lichtenberg et al., 2004). This might be the reason why 'hypnotic prone' individuals obviously showed markedly higher scores in charming ('charming/histrionic') and optimistic ('optimistic/rhapsodic') personality traits. This special attitude of social approachability of high hypnotizables (in case that they are securely attached; see Peter et al., 2014) can obviously also be artificially created by oxytocin administration (Bryant and Hung, 2013) or by disrupting the dorsolateral prefrontal cortex with low frequency repetitive transcranial magnetic stimulation (Dienes and Hutton, 2013) – i.e., a temporal enhancement of (state) hypnotizability. Furthermore, according to recent data (Geiger et al., 2014), hypnotizability seems to be positively correlated with intelligence after all, at least in women; the negative correlation found in men might explain why this association was not found in earlier studies.

Hypnotic Trance

Suggestions presented in hypnotizability scales are normally preceded by a so-called hypnotic or trance induction, during which the person is invited – after some introductory and explanatory words – to relax and enter a hypnotic trance. The benefit of using trance induction procedures has been discussed controversially. According to Braffman and Kirsch (1999), hypnotizability test scores were improved by preceding trance induction only in a small part of subjects, and only marginally so. The hypnotic induction showed no effect for about half of the subjects' and in fact a negative effect for a quarter of the subjects. Does this mean hypnosis induction rituals are expendable or even detrimental in some individuals? From a socio-cognitive perspective, trance induction works by creating expectancies of how one will response to the subsequent suggestions, and these expectancies make it easier for subjects or patients to use their suggestibility for achieving the aims of hypnosis. Hence, in clinical practice, hypnosis is preceded by a shorter or longer, direct or indirect induction of a hypnotic trance, before actual suggestions are implemented during hypnotherapeutic work.

Both the wording and grade of elaboration in presenting the induction formula are of particular importance for the effect of the subsequent hypnotic suggestions. For example, responses to suggestions in hypnotizability scales are less pronounced if introducing words convey the expectation that relaxation is induced rather than hypnosis (Gandhi and Oakley, 2005). Obviously, highly hypnotizable individuals need to hear precisely what they should be doing, that is, whether they are expected to relax or to enter a hypnotic trance. Culturally shaped meanings imply that these two are not exactly the same. High hypnotizables seem to respond easily to simple direct suggestions while medium hypnotizables need longer and more elaborated suggestions (Szabó, 1996), like the so-called indirect approaches in Ericksonian hypnosis, such as conversational inductions, embedded commands, or therapeutic metaphors.

Neuroimaging studies show that, in highly hypnotizable individuals, the induction of a hypnotic state is accompanied by changes in brain activity. These changes consist mainly of decreased activation of certain prefrontal regions (Dietrich, 2003; Egner et al., 2005) and relate to the so-called default mode network (DMN; McGeown et al., 2009). With this, the old controversy in hypnosis research between state theorists and nonstate theorists (e.g., socio-cognitive theorists) seems to be resolved, at least insofar as the latter denied the existence of a specific hypnotic state. However, the significance of the effect of hypnotic induction in relation to hypnotizability is still unclear (e.g., Mazzoni et al., 2012).

Hypnotic Phenomena: Practical Uses and Scientific Results

Hypnotic phenomena are characterized by changes in perception, experience, cognition, and behavior, which are different from an individual's everyday experience, and different from deliberately produced imagination. Accompanied by psychophysiological and neurophysiological concomitants, they exhibit a high degree of evidence, so that they can be experienced as actual hallucinations or illusions. This can be called the ratification of a hypnotic trance.

Hypnotically suggested behaviors are perceived to have a high degree of involuntariness or automatism. The experience of agency and the perceived control of an action should be significantly altered, sometimes right up to the experience of an alien control. In addition to the feeling of evidence of the imaginations, the perceived involuntariness of the suggested action is an essential element to the experience of being hypnotized. By involuntariness, the hypnotized person indicates that she/he willingly transfers the agency of her/his actions to another agent and allows a kind of alien control. Without voluntary help, a suggested action can occur (such as an arm lifting without voluntary effort following a suggestion for arm levitation) or an action may not be executed in spite of deliberate effort to do so (a cataleptic arm cannot be bent, or one's eyes, when closed, cannot be opened willfully). These are classical dissociative phenomena, which are typically perceived as unusual or unfamiliar and therefore attributed to the state of being hypnotized. The connection of two in everyday life's continuous mental processes is interrupted, such as that between intention ('I want to open my eyes') and execution ('I can open them').

The important factor is the exact attribution of this source of alien control because it conveys, among other things, the preconceived notion that hypnosis is operated by a 'lack of will,' in the case of the 'hypnotic power' of a stage hypnotist. A neutral attribution in scientific studies, for example, usually refers to the hypnotizability of the subject. In the psychotherapeutic context, an internal locus of reattribution is exclusively appropriate, such as one's unconscious resources, the power and capabilities of the unconscious mind, or unconscious creativity, in order to expand a patient's sense of self-efficacy.

The classic hypnotic responses (hypnotic phenomena), which are also produced through hypnotizability assessments, can be categorized according to phenomenological aspects into the following groups.

Motor-Kinesthetic Phenomena

Motor-kinesthetic phenomena consist of so-called ideomotor behaviors, which are experienced as involuntary (e.g., hand levitation, eyelid closure), catalepsy, or paretic inhibition of behaviors. Most people can experience motor-kinesthetic phenomena, which do not typically require a high degree of suggestibility (Peter et al., 2013). Direct suggestions for ideomotor movements, such as for eye closure or arm levitation, are more easily and often followed than suggestions for the lack of bodily mobility, which challenge one's personal agency, such as eye catalepsy (the eyes cannot voluntarily be opened) or entire bodily paralysis (the muscles cannot be moved willingly).

The psychotherapeutic object for a full body paralysis through motor inhibition accompanied by sensory deprivation through eyelid closure can be seen in facilitating the construction of an alternative reality by increasing the capacity for imagination and deepening the absorption. Thus, the prerequisites for classical (Pavlovian) conditioning are created, i.e., for psychophysiological and emotional learning. If one's

own cause of an action cannot be experienced because of a catalepsy or paresis, the question arises as to whom or to what agency and control has been transferred. In the history of hypnosis, this is traditionally a 'therapeutic Tertium (third),' whose special form is shaped by socio-cultural beliefs. The contemporary gestalt of this therapeutic Tertium are the 'unconscious' resources of a person, which are often summarily referred to, especially in the context of Milton Erickson, as 'the unconscious' or, as is the actual traditional term, the 'subconscious' (Dessoir, 1896). The ritual of arm levitation is well suited for making this therapeutic construct of the unconscious available and to get in contact with it ("The more you come in contact with your unconscious, the higher goes your arm…"), such as through ideomotor signaling ("If your unconscious mind knows the answer to the question XY, then the right hand goes up; if not, the left hand…"). Through this or a similar therapeutic Tertium (unconscious knowledge, inner wisdom, hidden resources, etc.; see Peter, 2009a), a patient's sense of self-efficacy can be restored and strengthened. In some severely disturbed patients, when suitable internal resources are lacking, a targeted therapeutic input is necessary. But even in this case, the form of a 'representative' figure (Bongartz and Bongartz, 2009) can be introduced and integrated into the patient's reservoir of abilities.

A series of research studies have shown that motor-kinesthetic phenomena are not mere compliance reactions. Peter et al. (2012a) were able to demonstrate that electromyographic (EMG) muscle activity of the deltoid muscle during hypnotically induced arm levitation was 27% less than deliberately lifting and holding up the arm without hypnosis. Neurological studies have shown that the perception of involuntariness and alien control activates different parts of the brain than deliberate initiation and control of the movement. Blakemore et al. (2003) found activation of the parietal operculum only when an ideomotor arm levitation following a hypnotic induction was externally attributed. Pyka et al. (2011) found that a change in the authorship of an action (i.e., perceived control or agency) was associated with a change in the region of the neighboring angular gyrus. In a recent exploratory study, Deeley et al. (2013) showed brain images of ideomotor movements while using a joystick: Loss of perceived control of movements was associated with reduced connectivity between supplementary motor area and motor regions. In addition, reduced awareness of involuntary movements were associated with less activation of parietal cortices (BA 7), which are thought to be responsible for awareness of the bodily self and for somatosensory awareness (Insula).

Sensory-Affective Phenomena

Sensory-affective phenomena include positive and negative hallucinations (or illusions) among all sensory modalities. These phenomena can be experienced by fewer people, which, among other things, depend on the sensory modality that is suggested to be hallucinatory or illusory, and on whether the experienced hallucination is challenged by external evidence. Positive visual phenomena (e.g., hallucinating a nonexistent person), for example, are easier to experience for more people than negative visual phenomena (e.g., a real existing person cannot be seen) or a combination of negative and positive olfactory hallucinations (e.g., to enjoy a strong ammonia smell as a sweet scent of violets). Taste hallucinations (a sweet or sour taste in the mouth) are, in turn, easier to hallucinate than positive auditory hallucinations (e.g., listening to music). The latter is, in turn, easier than hallucinated auditory deafness (e.g., one can no longer hear an actual speaking voice).

These phenomena find their traditional use in medical and dental applications, especially for hypnotically induced pain control; an efficient hypnotic anesthesia is by definition a negative-kinesthetic hallucination. The hypnotic amelioration of pain is, however, dependent on a patient's (trait) suggestibility and of the special features of a given pain. The hypnotic control of somatosensoric aspects of pain is, for example, more dependent on a patient's existing suggestibility, in contrast to the change of the affective parts of psychosomatic pain.

In psychotherapeutic practice, these sensory-affective phenomena depend highly on the personal meaning or the affective significance of the patient and, therefore, contribute to his/her (state) suggestibility. In trauma therapy, for example, one can regain control over intrusions through numerous uses of positive and negative hallucinations and illusions: Using all modalities and qualities of the senses and through spatial orientation, the imagination of a 'safe place' as a hallucinated alternative reality should first be constructed. The next part consists of a planned deconstruction of the traumatic experience. Those aspects of hallucinated perceptions and exuberant emotions are dissociated with the help of negative hallucinations so that they can be better processed cognitively and emotionally. Only then does a gradual confrontation with the traumatic event become useful in order to establish a new interpretation and subsequent reintegration into one's biography. Generally speaking, each hypnotic age regression entails positive and negative illusions and hallucinations, i.e., many different sensory-affective phenomena, which are based on real episodic and procedural memories from one's personal history, or are entirely constructed in therapy ('created memory'). This is especially useful when maladaptive representations of a patient's biography must be reconstructed in order to view certain aspects of the past from a more adaptive perspective. This possibility, with the help of hypnosis or even by virtue of a given high suggestibility, of creating paramnesic phenomena has led to major controversies and law trials in the 1990s on the advantages of hypnotically uncovering 'repressed memories' versus the danger of the implantation of profound 'false memories' (cf Spiegel and Scheflin, 1994).

There are now numerous studies that show that the perceived quality of sensory phenomena is verifiable through neurophysiological studies (e.g., cf Peter, 2009b). Such studies prove that sensory phenomena are caused not simply by a mechanism of distracting one's perception but are the product of profound dissociative processes (cf Friederich et al., 2001). A basic neural mechanism for dissociative hypnotic phenomena, which play a role in negative hallucinations or illusions, seems to be that established normal functional connectivity networks are suspended by appropriate hypnotic suggestions, so that there will be a disruption in the synchronization of relevant areas of the brain that effect some action or

perception (for pain, see Miltner and Weiss, 2007; Rainville et al., 1997). In contrast, those functional connectivity networks, which constitute a perception in normal circumstances, are activated when suggestions for positive phenomena are given (e.g., see Derbyshire et al., 2004 with respect to pain; Kosslyn et al., 2000 for visual illusions).

Cognitive Phenomena

Most textbooks consider the sensory phenomena as cognitive phenomena. In the phenomenological classifications established here, cognitive phenomena are limited to explicit cognitive deficits, such as partial amnesia (e.g., following a suggestion to 'forget' a number, one cannot perform an arithmetic problem in which that number appears) or following, with seeming compulsivity, a given posthypnotic suggestions (e.g., upon a previously established signal, for which source amnesia is suggested, one reproduces a suggested hypnotic phenomenon following the termination of hypnosis). More complex phenomena that resemble neurological or psychiatric disorders and include sensory phenomena are self-referenced illusions, such as being unable to recognize one's own reflection in the mirror or believing it to be that of an opposite sex fraternal twin (Cox and Barnier, 2013).

In the so-called golden era of hypnosis in Europe at the end of the nineteenth century, one thought that psychotherapeutic change could occur simply with phenomena such as amnesia and posthypnotic suggestion. However, one came to find that both were rare and relatively ineffective for many patients. Today they do not play a dominate role in hypnotherapy, at least not in the form of direct suggestions ("You will forget that for decades you have been a heavy smoker, and you will become nauseated whenever see a cigarette or smell cigarette smoke" – given the variety of smoking-related stimuli in an everyday environment, one would likely become desensitized to such a suggestion). More conceivable for psychotherapy are suggestions that are aimed at more complex changes in the self-concept of a person ("You are leaving your old lifestyle as a smoker behind you and develop a new self that can easily refrain from smoking").

That last example exemplifies that hypnosis in psychotherapy is not something in which the patient will follow well-intentioned suggestions without criticism or resistance. Rather, he should be encouraged to change more or less extensively and even profoundly his/her self-concept and conviction about his/her capacities to think, experience, and act along with his social role. This, actually, is not a new concept as the classical theory of suggestion already stated that any heterosuggestion must be accepted autosuggestively in order to be effective (Langen, 1972: p. 7).

Various findings suggest that hypnosis shifts the balance between anterior effector and posterior sensory processing (Spiegel and Kosslyn, 2004). This can also be substantiated, based on recent data, as to the so-called DMN (e.g., see McGeown et al., 2009). The DMN is usually in a deactivated state when the brain is occupied with external tasks. It is activated when there are no external tasks to which to tend and a person has the time and inclination to let one's mind wander and lead in internal self-talk. In particular, the posterior portions of the DMN, the precuneus, and the posterior cingulate are regarded as the cortical correlates of self-referential processes, which are substantially involved when one constructs a mental image of oneself (Raichle et al., 2001). Following a hypnotic induction, the anterior portions of the DMN in the prefrontal cortex specifically seem to be deactivated. To that effect, McGeown et al. (2009) believe that the hypnotic situation followed by further suggested tasks will be inferred by subjects as an external task. In psychotherapeutic terms, the trance induction seems to contribute to the ceasing of the patient's negative self-talk and prepares him/her to attend to another's voice that offers alternatives for cognitive restructuring (Kraiker, 1985). Results of Cojan et al. (2009) and Pyka et al. (2011) show a significant activation of the posterior portions of the DMN when special hypnotic tasks are desired. These studies have shown, for example, that hypnotic paralysis is not caused by a direct inhibition of motor centers by the orbitofrontal cortex, as Ward et al. (2003) have shown. Rather, a hypnotically induced immobility is apparently mediated by the precuneus and thus possibly due to an extensive change in the self-representation of the hypnotized person. The suggestion for paralysis would not be interpreted strictly in the sense of "My arm is paralyzed" – the results of Ward et al. (2003) might stipulate that – rather it is much more complex like "I am hypnotized and have been told that my arm cannot move, thus I cannot move it." One can hope that future clinical studies will show that more comprehensive hypnotherapeutic changes in self-concept, particularly in depressive or anxious patients, will correspond to analogue changes in the brain.

Ability to Hypnotize

One could assume that it takes some skill or ability to use hypnosis that might go beyond the mastery of techniques. This is still a largely unexplored area. Our own results indicate that successful users of hypnosis possess the previously described hypnotic prone personality style and have good personal experiences with hypnosis (Peter et al., 2012b).

Context of Hypnosis

In contrast, the numerous contextual factors that may influence the degree of a subject's or patient's hypnotizability have been well investigated by a variety of social psychological studies. It is obvious that task related motivation and expectations (see Lynn et al., 2008) are important factors, not only for highs but also for medium suggestible people, in order to experience hypnotic phenomena. The so-called indirect hypnotic techniques of Milton H. Erickson, particularly the elaborate instructions used to create and use hypnotic rapport, the therapeutic relationship in the hypnotic context, serve this purpose (see Rossi, 1980; for further details).

Techniques and Rituals

The techniques and rituals of the hypnotic induction as well as the subsequent utilization of the hypnotic trance state for

certain purposes, such as in medicine or psychotherapy, are very simple in its direct form. They are easy to learn and require no prerequisites. The techniques are described in detail in many manuals. In a simple, direct form, they are obviously on the hypnotizability of the subject or patient. Depending on the hypnotic phenomenon, they may only be suitable for high hypnotizables and only with limited effectiveness. The large number of medium hypnotizables requires techniques that present the necessary phenomenon in an elaborate form (Szabó, 1996). This function can be fulfilled by the indirect techniques created by Milton H. Erickson and his followers (Revenstorf and Peter, 2009).

Areas of Application

When hypnosis is used in the field of medicine or dentistry, it is referred to as clinical or medical/dental hypnosis, while it is referred to as hypnosis therapy or hypnotherapy, and sometimes therapy in trance, when used in psychotherapy. The use of hypnosis has increased since the end of the last century in medicine, dentistry, and especially in psychotherapy in German speaking countries as well as in other European and in English speaking countries. Since the 1990s, a special focus has been placed on the use of the so-called Ericksonian hypnosis or hypnotherapy. The scientific evidence regarding the efficacy of medical hypnosis is good, but unsatisfactory in the field of hypnotherapy (for more details see Hagl, 2013, 2014).

The still valid meta-analysis of the efficacy of hypnosis conducted by Flammer and Bongartz (2003) incorporated 57 randomized control trials (RCTs), in which the clinical use of hypnosis was compared with untreated or treatment-as-usual control groups, and yielded a weighted effect size of $d = 0.56$. Approximately three quarters of the 57 studies (from the years 1973–2002) investigated the application of hypnosis for somatic complaints or as an adjunct to medical treatments. Studies on affective and obsessive–compulsive disorder, however, have been lacking since the 1970s. There were some studies of anxiety disorders, which focused mainly on test anxiety with an effect size of $d = 0.69$, and seven studies on smoking cessation, which had an effect size of $d = 0.59$. A further meta-analysis by Flammer and Alladin (2007) of 21 RCTs considered only trials for the treatment of psychosomatic disorders that had a weighted effect size of $d = 0.61$. In general, the use of hypnosis in medicine is considered to be rather effective. The effectiveness of hypnosis for the reduction of experimental and clinical pain is considered good (Montgomery et al., 2000). The effectiveness of reducing anxiety and stress prior to surgical and other medical invasive procedures is well documented. Tefikow et al. (2013) calculated of 34 studies, small to medium effect sizes: $g = 0.53$ for the reduction of psychological stress, $g = 0.36$ for pain intensity, $g = 0.56$ for impairment caused by pain, and $g = 0.36$ for drug consumption. These results prompted the *Wissenschaftliche Beirat Psychotherapie* (WBP; Scientific Advisory Board) of the Federal Republic of Germany to pronounce the recognition of hypnotherapy as a treatment for the ICD diagnosis group F54 (mental and social factors in somatic disease) in 2006; this implies that the use of hypnosis is financed by legal and private health insurance.

There is a particularly diverse and extensive collection of individual reports and case studies for the use of hypnosis with dissociative, posttraumatic stress, and anxiety disorders. There are only a few reports for the treatment of obsessive–compulsive disorder and even fewer for depression alone. For anxiety disorders, the evidence of effectiveness is focused mainly on hypnotherapy for patients with test anxiety. In a meta-analysis of eight studies (Flammer, 2006) in which hypnosis was compared with a placebo of simply paying attention to patients, there was a medium effect size of $d = 0.66$. Another eight RCTs compared with a waiting list control group had an effect size of $d = 1.02$. There are only two controlled studies for posttraumatic stress and acute stress disorders, which showed a slight superiority of hypnosis compared to psychodynamic (Brom et al., 1989) or cognitive behavioral therapy (CBT; Bryant et al., 2005). For affective disorders, only one study thus far has met RCT standards: Alladin and Alibhai (2007) compared the combination of hypnosis with CBT and CBT alone, and found the former was slightly superior. In an older meta-analysis, Kirsch (1996) found a substantial effect of hypnotherapy for eating disorders when hypnosis was used in addition to behavioral weight loss programs. More recent data are not available.

There is some controversy over the results with substance dependence, particularly in regard to the value of hypnosis for smoking cessation. A Cochran study (Barnes et al., 2010) was judged to be ineffective. The WBP (2006) in Germany, however, has scientifically recognized hypnotherapy for smoking cessation (as well as methadone withdrawal). Still, the overall effectiveness of hypnosis for psychic disorders is largely not well proven by RCTs.

Another application of hypnosis is within the area of basic scientific research, referred to as scientific hypnosis. Researchers from other psychological disciplines, such as bio- and neuropsychology, make use of hypnotic techniques to investigate cognitive and emotional phenomena, often in the last two decades with the aid of brain imaging.

Stage hypnosis, in which hypnotic techniques are used for entertainment purposes, is still being used to the chagrin of almost all professional users of hypnosis. With the exception of a few countries such as Israel, Sweden, and Denmark, it is not illegal in most countries. Lay applications of hypnosis for show as well as healing purposes can be seen throughout the entire history of hypnosis as an accompanying phenomenon.

History

Hypnosis has a long history and is sometimes seen as the mold for all forms of psychotherapy, and it certainly applies for all psychodynamic therapies. Behavioral therapies date back to other sources, particularly with respect to experimental and learning psychology. The physician Franz Anton Mesmer, with his theory of animal magnetism, is often considered to be the great grandfather of modern hypnosis. This, however, has to be doubted for several reasons. His

theory postulates a universal fluid, animal magnetism, of which the flow is disrupted in ill people and had to be harmonized though certain physical applications such as the so-called passes or through a baquet. This theory has nothing to do with the modern understanding of psychotherapy. During the Romantic Era of the first third of the nineteenth century, the understanding of the original physical magnetism as conceived by Mesmer changed basically. The still practiced passes were no longer thought to transfer a physical force but to create a special somnambulistic state, which empowers the sick with special abilities, such as self-diagnosing and self-therapy. From a modern view, one could see this as a rudimentary concept of orientation toward the resources of the patient. This new and even more psychological understanding of the 'magnetic rapport' dates back to Puységur, who was one of Mesmer's students and first formulated the approach that was 100 years later elaborated by Janet and Sigmund Freud at the end of the nineteenth century. It is referred today as the therapeutic relationship and is thought to play an important role in psychotherapy and hypnotherapy (Peter and Iost-Peter, 2014). Mesmer's original ideas continue to live today in many lay and healing practitioners as fluidists and magnetists. Lay magnetists and lay hypnotists were an inseparable part of the history of hypnosis; they continued the techniques when they were forgotten in professional circles and even banned from them. James Braid, for example, developed his idea of monoideism – induced nervous sleep (Neurypnology, from which the term hypnosis is derived) – from a lay magnetist. Freud was impressed by the stage hypnotist Hansen in Vienna, then later learned eventually at the end of the nineteenth century from Jean Martin Charcot in Paris and Hippolyte Bernheim in Nancy. The theory of the latter about the effect of hypnotic suggestion would dominate the basis on scientific research of hypnosis starting in the 1920s by Clark Hull (cf 1933) in Wisconsin and later at Yale and Ernest Hilgard (cf 1979) in the 1960s at Stanford. Milton H. Erickson was a student of Clark Hull and developed a very divergent opinion about hypnosis: instead of standardizing the suggestions, as Hull used and demanded particularly for the purposes of research, the hypnotic inductions and suggestions should be adjusted to the needs and individual possibilities of each hypnotized person. From this, he developed, with great creativity, a variety of elaborate verbalizations for suggestions and suggestive strategies for therapeutic change, which are known today as the so-called indirect or Ericksonian hypnosis, and are indispensible to modern hypnotherapy. As mentioned previously, the major advantage of these techniques is that hypnosis can be used with more patients, namely those who are of medium suggestibility. Thus Erickson becomes the father of modern hypnosis and hypnotherapy. If one wants to find the great grandfather of today's psychotherapy and hypnosis, then the Exorcist Johann Joseph Gassner fulfills this role better than Franz Anton Mesmer because his special form of exorcism involves many elements of hypnotic rituals and also comprises the important principles of behavior-therapeutic self-control (Peter, 2005).

Abstract

Hypnosis has long been used as a healing practice and is still used for therapeutic purposes. Initially, hypnosis was studied in nonhuman animals and humans using electroencephalograms. New brain imaging techniques such as functional magnetic resonance imaging allow for a better understanding of neural activity patterns during hypnosis. These studies have revealed that attention and default network activity are altered in hypnosis. Specifically, activity patterns point toward a systems view of hypnosis that discounts a unitary state hypothesis. Future imaging research might be directed toward investigating these neural correlates within the framework of a two-system approach.

Introduction

The following article will give a brief overview of the origins of hypnosis. After the historical account, the therapeutic uses will be discussed along with an account of the current state of the literature on its neural correlates. Subsequently, animal hypnosis will be briefly described, followed by an account of the role of cognitive control and attention in hypnosis. The final sections will discuss some limitations of current methodologies for testing and a proposal for future research.

A Brief History of Hypnosis

The term hypnotism was coined by the English surgeon James Braid, the so-called *father of hypnosis*, in 1842 (Charcot, 1889). However, hypnosis had been used as a healing practice long before that time. Early accounts of its practice date back to 200 BC, when yogis in ancient India described transcendental meditation (Jaltare and Gopinath, 2012). Hypnosis was publicized during the time of the German physician Franz Anton Mesmer (1734–1815); it was then known as *animal magnetism*. This term coined by Mesmer described the reciprocal transference of energy that occurred between animate beings, which Mesmer believed to house a certain *life energy* or *ethereal fluid* (Crabtree, 2012; Waterfield, 2003). It was through Mesmer's highly controversial, but highly publicized treatment of diseases with magnetism, that hypnosis as a practice became popularized. Mesmer's work in the mid-eighteenth century can be considered the basis of Western hypnosis as it is contemporarily understood, and the colloquial term *mesmerized* originated directly from his name (Waterfield, 2003). Mesmer's healing technique involved sweeping motions of the hands over the body of a patient in order to apply what he thought was the power of the magnetic fluid (Crabtree, 2012).

Mesmer's student Puységur noticed that a magnetized person typically displayed six characteristics: (1) an altered state of consciousness that resembled sleepwalking; (2) a special connection with the person performing the magnetism; (3) suggestibility (i.e., the performance of suggestion and the susceptibility to such suggestion); (4) amnesia of the events occurring during magnetism; (5) ability to read the thoughts of the magnetizer; and (6) personality change during magnetism (Crabtree, 2012). Puységur further described this altered or divided state of consciousness as *magnetic sleep* or *somnambulism*, as he believed that this state was the same as natural sleepwalking. He did not himself believe in the magnetic fluid that was central to Mesmer's theory, and instead focused on the psychological aspect of rapport between the magnetizer and the patient. Around the time Puységur started his own practice in 1784, Mesmer's healing techniques were deemed nonscientific by a French scientific commission who argued that Mesmer's practice dealt with imagination, not physical entities (White, 1941).

In the nineteenth century, when the English surgeon Braid had learned about magnetism, the terminology shifted from magnetism to hypnotism (Crabtree, 2012). In fact, Braid initially used the term neurohypnotism, of which hypnotism is an abbreviation. He believed that the phenomena produced by hypnosis were purely physiological, and that the mind slipped out of gear when fatigued by any lasting sensation. It was in that state that the patient was rendered susceptible to hypnotic direction. As Crabtree (2012) points out, hypnotism was not popular in England during Braid's lifetime, but was readily adopted in France and in the United States.

At the turn of the twentieth century, hypnosis became popularized through the Nancy School of hypnosis initially through Hippolyte Bernheim, whose focus was the role of suggestion in hypnosis. Other European neurologists and psychologists, including the French neurologist Jean-Martin Charcot at the Salpêtrière hospital and his student Sigmund Freud, soon opposed Bernheim's focus on suggestion. Conversely, Charcot considered hypnosis a neurosis, the states of which were naturally derived, and not brought about by suggestion. Charcot delineated three different states: (1) cataleptic state, (2) lethargic state, and (3) somnambulistic state. At this time, the terminology of neurosis was heavily used in the new psychoanalytic theory, of which Freud and Charcot were avid proponents. Indeed, Charcot

considered hypnosis an artificially created neurosis, which was identical with hysteria (Crabtree, 2012). Both the Nancy and Salpêtrière schools of thought coexisted at the time, but it was Bernheim's theory that resulted in the dominant views about hypnosis and suggestion.

Since the mid-1900s, increased efforts have been directed at the scientific study of hypnosis. The American psychologist Robert White (1941) saw hypnosis as an experimental technique by which to reorganize the behavior of a person, which in turn allowed for the study of artificially reproduced behaviors and a variety of psychological problems. White also highlighted the fact that hypnosis allows for studying individual differences in behavior, as the technique generally did not elicit the same phenomena among individuals. He proposed that hypnosis be part of social psychology, and asked scientific questions about the phenomena that it encompasses. In short, White (1941) considered hypnosis as a meaningful, goal-directed striving. In the 1990s, a sociocognitive perspective on hypnosis purported by the American psychologist Nicholas Spanos emerged (Crabtree, 2012). His explanations of hypnosis held that the patient or participant enacts a role. The experimenter and participant subsequently interact during the state of hypnosis via subtle cues.

Today, researchers continue to attempt to understand the underlying mechanisms of hypnosis. One controversy that has remained is whether hypnosis presents an altered state of consciousness, or whether it is an ordinary psychological process related to others including role enactment, imagination, relaxation, and attention (Jaltare and Gopinath, 2012; Karlin and Orne, 2001; Kluft, 2012). There have been two camps of hypnosis researchers. The first camp proposes that hypnosis is a discrete, unique state of consciousness (Raz, 2011). The second camp ascertains that hypnosis is a form of common wakefulness rather than a discrete state. This debate will be touched upon again toward the end of the article. First, however, some contemporary uses of hypnosis as a therapeutic means will be discussed.

Therapeutic Hypnosis

Hypnosis is currently used for various therapeutic treatments, including pain management and cessation of addictive behaviors. The following section will elucidate the role of hypnosis in such treatments in greater detail, as it is widely used and known to laypeople through its therapeutic applications. In Mesmer's days, both mineral magnetism, which was performed using magnets, and animal magnetism were used as therapy for ailments such as convulsions, blindness, asthma, edema, and other nervous complaints (Oon, 2008). Mesmer himself acknowledged that there were some limitations to which illnesses or symptoms could be cured via hypnosis. These were largely restricted to nervous disorders, whereas *organic* or permanent conditions could benefit indirectly, such as via improvement of the patient's mood (Oon, 2008).

Pain management is one area in which hypnosis is most often used. A review by Askay et al. (2009) highlighted the use of virtual reality hypnosis in pain management. The authors explained the advantages of virtual reality hypnosis, including: (1) diminished dependency on a trained, skilled hypnotist; (2) cost-effectiveness; and (3) superiority to audio hypnosis. In virtual reality hypnosis for pain treatment, a patient enters a virtual, three-dimensional world via virtual reality technology. Askay et al. (2009) argued that the patient thereby enters a *presence*, attention becomes focused toward that presence and away from the pain. For instance, research also found that virtual reality hypnosis was successful for treatment of acute pain after burns (Patterson et al., 2004) and of chronic neuropathic pain (Oneal et al., 2008). Further, in participants with low hypnotizability (i.e., the trait measure assessing a person's ability to be hypnotized; Hilgard and Hilgard, 1975), hypnotizability was enhanced through virtual reality hypnosis (Askay et al., 2009). The authors proposed that this feature of attention capture combined with hypnotic suggestion may be an ideal way to approach pain management. Indeed, in healthy participants undergoing pain stimulation, virtual reality hypnosis was associated with a reduced pain-related functional magnetic resonance imaging (fMRI) signal in the anterior cingulate cortex, insula, thalamus, and primary and secondary somatosensory cortices (Hoffman et al., 2004).

Another way hypnosis can be used is by administering it oneself. That is, rather than having a dedicated hypnotist perform the suggestion, patients are given the tools to hypnotize themselves. Self-hypnosis as a form of treatment for labor pain in women giving birth was recently investigated by Werner et al. (2012). While successes with this method had been previously reported (Martin et al., 2001; Mehl-Madrona, 2004), in this randomized, controlled trial, women using self-hypnosis as a pain management strategy were still found to use as many conventional pain management methods (e.g., epidural analgesia) as women who did not use self-hypnosis. Self-hypnotized women also reported a similar experience of labor pain compared to those who did not use self-hypnosis. The authors concluded that in previous studies, participants were self-selecting hypnosis for treatment of labor pain, and therefore may have had systematically different characteristics prior to the intervention. The use of a randomized, controlled, large-size trial in the study by Werner et al. (2012), however, did not allow for a self-selection bias, and thus may not have found any treatment effects.

A recent randomized, controlled study investigated the underlying mechanisms of hypnotic intervention in pain management (Goodin et al., 2012). The authors examined pain ratings, as well as pain-provoked changes of cortisol and the soluble tumor necrosis factor-α receptor II (sTNFaRII) after intervention with hypnosis. Highly susceptible participants were randomly assigned to an experimental group who received intervention with hypnosis, or to a control group. The authors found that pain ratings were significantly reduced in those participants undergoing hypnosis, but neither cortisol nor sTNFaRII levels were reduced in reaction to acute pain. Because effect sizes were moderate in the pre- to post-intervention assessment, the authors did not rule out a role of the hypothalamic-pituitary-adrenal (HPA) axis altogether and concluded that future research was needed to further investigate how hypnosis might affect chronic pain as evidenced by a dysfunctional HPA axis.

Jensen et al. (2012) reviewed the use of functional neuroimaging to evaluate pain treatments including hypnosis. The authors stated that psychological pain treatments have gained

greater popularity either as a standalone method or in combination with pharmacological treatments. Among these treatments are distraction techniques, clinical hypnosis, and mental imagery. In typical hypnotic suggestion for pain relief, the patient initially receives suggestions for: (1) relaxation, followed by subsequent suggestions for one or more of (2) distracted attention, (3) positive affect, and (4) heightened self-efficacy to install a feeling of control over the pain (Green et al., 2005; Jensen et al., 2012). As this article reviewed some of the neuroimaging techniques including fMRI and positron emission tomography (PET), it allowed for an indication of underlying neural correlates. From this review, the following correlates of psychological pain modulation became evident in healthy participants undergoing pain stimulation: dorsolateral and ventrolateral prefrontal cortex (dlPFC, vlPFC), anterior cingulate cortex (ACC), and periaqueductal gray (PAG). In particular, ACC activity was shown to correlate with modifying pain unpleasantness, and activity in primary somatosensory cortex (SI) has been shown to correspond with modifying pain intensity (Rainville et al., 2002). However, in patients with chronic pain such as fibromyalgia or chronic back pain, when pain was modulated via hypnosis, no corresponding activity specifically in ACC, but rather a unique change in overall activity patterns occurred (Derbyshire et al., 2009; Nusbaum et al., 2011).

Lastly, Hill (2010) reported several studies by Ernest Rossi, who unprecedentedly investigated the epigenetic changes associated with hypnotic intervention, which he initially called *psychosocial genomics*. Genes related to well-being and health were reportedly expressed in the hours and days after hypnotic intervention. Using deoxyribonucleic acid (DNA) microarrays, Rossi and colleagues (Atkinson et al., 2010; Rossi et al., 2008) were able to assess epigenetic changes brought about by experience-dependent gene expression. Blood samples were obtained from participants to construct DNA microarrays prior to hypnosis, 1 h following hypnosis, and 24 h following hypnosis. After participants underwent hypnosis, epigenetic changes were assessed, as were subjective ratings of hypnosis using the Stanford Hypnotic Susceptibility Scale (SHSS; Hilgard, 1965). In a pilot study (Rossi et al., 2008), upregulation of 15 genes was found. Some of these genes were characteristic of stem cell growth and proliferation, plasticity associated with memory, learning, and novelty, and stress reduction (Hill, 2010).

In summary, while hypnosis seems to be effective for treatment of pain in healthy participants who undergo pain stimulation, the story tends to be more complicated for those with chronic pain (Jensen et al., 2012; Nusbaum et al., 2011) or acute labor pain (Werner et al., 2012). Additionally, physical markers of pain modulation such as cytokines and cortisol have not shown modulation through hypnosis (Goodin et al., 2012). However, pain management via hypnosis can possibly elucidate some of the underlying neural correlates of hypnosis. In particular, in healthy participants undergoing pain stimulation, distinct neural activity markers were found during pain treatment (Rainville et al., 2002). Specifically, many areas involved in the so-called *default network* tend to show activity during hypnotic pain modulation. In the following section, the role of cognitive control and attention in hypnosis will be discussed.

Hypnosis, Consciousness, and Cognitive Control

The State Debate

As mentioned earlier, the contemporary debate about hypnosis pertains to whether it is a discrete state or a continuum of an existing state. That is, are people who are hypnotized in a distinct state, which is different from other states of consciousness, or can the performances of those hypnotized be equally well achieved by others not hypnotized? Proponents of the state theory purport that hypnosis is a distinct state of awareness, which is: (1) characterized by heightened suggestibility, (2) enhanced imagination, (3) reduced cognitive control, (4) involuntary behaviors, and (5) that such a state will one day be demonstrated on the neurophysiological level (Waterfield, 2003). Opponents of the state theory propose that: (1) responsiveness to suggestion is a normal psychological phenomenon, (2) individual differences in responsiveness are due to a person's expectations and attitudes toward hypnosis, (3) hypnotic phenomena are within human abilities, (4) involuntary behaviors have an alternative explanation, and (5) no neurophysiological proof for a hypnotic state will be found. Even though the state theory has faced much skepticism in the last four decades, as Waterfield (2003) pointed out, the antistate theorists thus far have not been able to *disprove* the state theory.

An early view of the state theory of hypnosis was motivated by the fact that hypnotic procedures result in bizarre behaviors (such as often seen in stage hypnosis shows) that some perceived as exceeding the capabilities of nonhypnotized individuals (Crabtree, 2012). However, as Crabtree went on to explain, such instances are indeed not unique to hypnosis. He cited two examples. The first was of a patient at the dentist's office who under hypnotic suggestion did not report any pain while six of his teeth were pulled. The second was of a railway worker whose toes were severed when his foot was run over by a railway car, while he was hurrying to push a coworker out of the way of an oncoming train. He also reported no pain, and had no awareness that his toes were run over until several minutes after the rescue of his coworker. As can be readily seen from these accounts, bizarre behaviors alone do not qualify as a classification criterion for a hypnotic state.

One prominent view is that of Ernest Hilgard (Hilgard, 1992; Hilgard and Hilgard, 1975). He described a theory called neodissociationism, which stipulates that there is a hierarchy of control systems that operate at any given time in any given individual. Hypnosis serves the function of modifying this hierarchical arrangement so that some control systems become separated or *dissociated* from others. Abilities for different tasks of varying orders of magnitude, such as writing a letter or raising a family, are named *subsystems* (Waterfield, 2003). At any point in time, different subsystems may be active, whereas others may not be. A central control system monitors these subsystems. Then, dissociation occurs through separation of subsystems from each other or from the central control system (Waterfield, 2003). Hilgard (1992) also stated that the concept of consciousness is an illusion, as people engage in multiple behaviors all the time, and a conscious representation of this engagement is never complete. He saw awareness as a tool that shifted among aspects of these behaviors or of the external environment.

Especially interesting to Hilgard was the idea that some attentive processes can occur without awareness. Those were the processes that he described as dissociated from the conscious experience of the person.

In summary, the debate about whether hypnosis is a discrete state or lies on a continuum of normal psychological phenomena continues. The view of neodissociationism proposed by Hilgard and Hilgard (1975) provided a basis for studying neural correlates, which has been done since. The next section will discuss how initial electroencephalogram (EEG) studies in animals attempted to answer the question of whether hypnosis occurs as a dissociated neural correlate without its equivalent behavioral output. Further, the dissociationist view is present again in contemporary fMRI studies that focus on attentional processes and their dissociation from external events.

Toward a Neural Basis

Recent literature points toward the fact that the state debate has largely been a theoretical one, and that little attention has been paid to a neural basis (Crabtree, 2012; Deeley et al., 2012). To begin, one might ask the question about how a distinct state of hypnosis is separable from other states of consciousness. One pathway for answering this question may come from the field of animal hypnosis, which has been prominent since the time of Pavlov (Whishaw, 1984). The term animal hypnosis must not be confused with Mesmer's animal magnetism, which was derived from the Latin *animus*, spirit or mind. In animal hypnosis, animal actually refers to the living creatures. Specifically, animal hypnosis describes the immobilization of an animal, such as a rabbit, by holding it turned onto its back, until its' breathing becomes regular and it relaxes its limbs. The animal will stay immobile for a period of up to 5 min (Whishaw, 1984). The brain activity accompanying such a hypnotic state in an animal is similar to the waking state activity of an animal that is sitting still. One theory of what happens in the hypnotic state is that the initial restraint of the animal activates a neural system in the brain that inhibits other neural systems that produce movement responses, which renders the animal immobile (Klemm, 1971).

Whishaw et al. (1982) set out to test which of two different EEG types that are present in normal rabbits can be observed during hypnosis. The authors explained that in the 1960s with the increased use of EEG, a new *state hypothesis* of animal hypnosis became popular. This hypothesis postulated that the animal is in a dissociated state in which EEG activity patterns are disconnected from the usual motor activity that accompanies them. In the example of the rabbit, two types of brain activity typically correlate with the animal's movements such as hopping, turning, and head movements. These activity patterns are classified as: (1) low voltage fast activity (LVA) and (2) hippocampal rhythmical slow activity (RSA, now better known as theta). These patterns can occur during movements such as those described above, and during resting state, or immobility. Immobility activity is typically of lower frequency. Whishaw et al. (1982) hypothesized that if higher frequency EEG activity was present in the hypnotized rabbit, then one could speak of a state dissociation brought on by the uncoupling of movement and movement-dependent EEG. If, however, the slower activity was present, then one could speak of hypnosis as a nondistinct state, as this activity can spontaneously occur during resting activity. Results indicated that only slower EEG activity found spontaneously in immobilized rabbits was present in hypnotized rabbits. Higher frequency activity could not be elicited through brain stimulation without accompanying movements, so a dissociation could not be achieved.

These initial accounts of animal hypnosis suggest that the state dissociation hypothesis is not supported by evidence derived from EEG in animals. The next section will discuss some of the correlates seen in fMRI studies in humans during hypnosis. These studies will focus largely on the default network, which in humans is an activity pattern that correlates with resting state activity. Because hypnosis tries to achieve a type of resting state, this framework has received particular attention. In fact, overlapping neural correlates between hypnosis and the default network have been found.

The Default Network and Attention

The default network, or default mode network (DMN), describes a network of brain structures that are more active during low-demand tasks or the brain's resting state, rather than being associated with specific tasks (Deeley et al., 2012). It can be described as an internal system, which is linked to self-related processes, and stands in opposition to the extrinsic system, which is linked to external stimuli (Demertzi et al., 2011). Deeley et al. (2012) pointed out that there are actually several networks involved in resting state activity, including the dorsal attention network, the sensorimotor network, and the DMN. The core regions of DMN consist of medial PFC, superior frontal cortex, ACC, posterior cingulate cortex, precuneus, and retrosplenial cortex, lateral parietal cortex, inferior parietal lobule, lateral temporal cortex, and parahippocampal gyri (Deeley et al., 2012; Lipari et al., 2012; Stawarczyk et al., 2011). These structures comprise networks that pertain to executive function and attention.

Activity in the DMN has been shown to be reduced during the resting state. Here, participants were instructed to lie quietly in an alert state or view a passive stimulus such as a fixation cross (Greicius et al., 2003). The amount of activity decrease has been shown to directly relate to the amount of cognitive demand required by the cognitive task. That is, DMN activity seemed to persist during a low-demand task, but it was reduced during a high-demand task. Similarly, DMN activity has also been shown to be reduced under hypnotic suggestion (Deeley et al., 2012). Demertzi et al. (2011) explained that reduction in connectivity during hypnosis among DMN areas including posterior retrosplenial, cingulate, and precuneal areas might be due to a decreased demand for interaction with the external and a focus toward the internal world. This explanation was supported by other findings (Greicius et al., 2003). This reduced connectivity along the frontoparietal axis might thus function as a way to eliminate sensory awareness in hypnosis. Another recent study showed evidence that this altered connectivity may underlie hypnotizability, as participants with high hypnotizability showed greater activity in the DMN (Hoeft et al., 2012).

However, Deeley et al. (2012) conceded that the cognitive and subjective correlates of the DMN are generally difficult to assess, as experimental interference may elicit unwanted goal-directed activity in this network. Thus, the authors proposed that hypnosis lends itself well to measure task-unrelated activity and its behavioral or cognitive correlates. Because participants can report self-ratings of hypnotic depth and further describe their experience in the alert state, these subjective accounts may be correlated to DMN activity.

Lifshitz et al. (2012) described that there are similarities in DMN activity between meditation and hypnosis, as both processes seem to rely on focused attention. Focused attention is the sustained narrowing of attention toward an internal aspect, such as breathing. Meditation, like hypnosis, has been shown to alter the neural expression of pain and also the connectivity in the default network. In a previous study by the same group, it was found that posthypnotic suggestion to perceive printed words as meaningless led to an increase in performance on a Stroop word-color task. This was correlated with a decrease in information processing in the visual cortex as well as a reduction in ACC activity (Raz, 2005). On this task, participants have to voice out the ink color of a written word, and not let the actual word, which spells out a different color to the ink, distract them. The posthypnotic suggestion by Raz (2005) thus improved participants' ability to pay attention to the color, rather than the word, which corresponded to a reduction in DMN activity. Long-term meditators too show this reduction in activity. This finding serves as evidence that focused attention is one common denominator of modulation in DMN processes. Attention is the common factor in both hypnosis and DMN processes, and it may be the case that this commonality lies in focusing attention inward to disregard external stimuli.

In an unprecedented study, Lipari et al. (2012) investigated DMN activity in an individual described as a *hypnotic virtuoso*, a very highly hypnotizable person who typically displays all phenomena associated with hypnosis. The authors deemed that this was an optimal participant to investigate pure hypnosis (i.e., hypnosis in the absence of possible distractions elicited by suggestion or mental tasks used to enter hypnosis). This study was motivated by the debate of whether hypnosis is a distinct brain state or not. Because wide individual differences even in DMN activity are seen during hypnosis, the neural correlates of pure or unconditioned hypnosis might give an insight into whether there is a unitary state that can be classified as hypnosis. Changes in the DMN were recorded using EEG and fMRI during task-free mentation of the hypnotic virtuoso. During hypnosis, there was increased activity in posterior regions of the DMN, including precuneus, posterior cingulate cortex, retrosplenial cortex, and inferior parietal lobule. Activity in the prefrontal regions of the DMN was also enhanced. This was in contrast to many studies, including those cited above, that typically found an activity reduction in anterior DMN regions, such as ACC and medial PFC. The authors explained that this could be due to the general mild hypnotizability of participants used in previous studies. In addition, this finding could be due to focusing attentional resources. This is in line with the internal focus of attention as it is steered away from external stimuli. The gathering of attentional resources may elicit activity in attentional networks, which are said to include PFC. In that sense, this case study of pure hypnosis may have provided a clearer picture of DMN activity during hypnosis.

As mentioned earlier, individual differences across participants in hypnosis have made it difficult to outline common features. Hoeft et al. (2012) investigated the functional basis for hypnotizability and found that many of these individual differences were due to the degree of participants' hypnotizability. Individuals who were highly hypnotizable showed greater activity in the dorsolateral PFC, which is a main hub in executive control. Further, there was increased connectivity between ACC and dorsolateral PFC in highly hypnotizable participants during the resting state. Compared with the resting state, highly hypnotizable individuals also showed decreased activity in ACC and dorsolateral PFC in hypnosis.

Priftis et al. (2011) tested the neuropsychological phenomenon of neglect in a posthypnotic suggestion experiment. Neglect typically follows damage to the parietal-frontal network in the right hemisphere, resulting in a complete unawareness of the contralateral (i.e., left) side of space and self. The authors explained that visuospatial attention can be deployed in two ways: (1) through a first subsystem, which is localized in the left hemisphere, and orients visuospatial attention from the left to the right, and (2) through a second subsystem, which is localized in the right hemisphere and orients visuospatial attention from the right to the left. The left-hemisphere subsystem is said to be more powerful. Neglect could thus be explained by citing these two subsystems. According to Priftis et al. (2011), neglect would be a result of ipsilesional hyperattention, rather than contralesional hypo-attention. To test this idea, posthypnotic suggestion was used in half the participants engaging in an attentional task. Indeed, neglectlike behavior was induced in participants under post-hypnotic suggestion. They further observed an asymmetrical allocation of attention to the right side of space, indicated by the fact that attention to the right visual field resulted in slower reaction times for stimuli shown in the left field compared to attention to the left visual field for stimuli shown in the right field. This finding supported the fact that neglect might be due to an ipsilesional hyperattention. It further corroborated the role of attention to hypnosis. During hypnosis, attention to an entire visual field was induced.

In a resting-state fMRI study (Pyka et al., 2011), the experimenter induced a left-hand paralysis in participants via hypnotic suggestion. Areas of the DMN were of particular interest, and fMRI analysis was based on these regions. Results showed that there was increased connectivity of the precuneus with the right dorsolateral PFC and angular gyrus. However, connectivity of the medial PFC and primary motor cortex was unchanged. The authors concluded that the precuneus was important for maintaining an altered state of consciousness.

Processes related to the DMN seem to be changed in hypnosis. This may indicate that hypnosis renders cognitive control processes such as attention to external stimuli unnecessary. Rather, cognitive control seems to be directed inward, which can explain some higher activation in the DMN toward hypnosis as observed by Lipari et al. (2012). Instead of surrendering to hypnosis, individuals indeed show enhanced control over sensorimotor function, but as Hoeft et al. (2012) point out, this is done with a sense of involuntariness and somewhat dissociated from the deliberation enabled through

cognitive control. This is consistent with the idea that through hypnotic suggestion, sensory experiences can be modulated, such as to decrease pain perception or reduce anxiety. Through this inward focusing of attention, it might be the case that awareness of external stimuli is diminished. Further, some attentional phenomena, such as visuospatial hemispheric neglect, can be induced via hypnosis (Priftis et al., 2011).

Even though many differences exist across studies in terms of methodology and in terms of which structures within or outside of the DMN show activity changes during hypnosis, there are some generalizations that can be derived from these accounts. First, activity changes in the DMN occur. In some cases, these changes present as an activity increase, and in other cases, as a decrease. There is no unequivocal consensus on which structures exactly are involved, but they typically present a subset of DMN structures. Second, attentional processes play a role in hypnosis. Attention is not a unified construct. Instead, many attentional processes can occur simultaneously. Attention can be focused on one stimulus, while others might go completely unnoticed (Crabtree, 2012; Hilgard, 1992). In hypnosis, it seems to be the case that some attentional processes are dissociated from external events and directed inward, as they occur in meditation. Third, cognitive control seems uncoupled from other systems in the brain, such as sensorimotor, visual, or auditory systems. Hypnosis can produce involuntary behaviors that are feasible during the normal state, but the executive control systems may be dissociated from them. That is, control over activation in subsystems in the brain is surrendered, or simply not attended to. Combined, these results point toward a systems view of hypnosis that discounts a distinct or unitary state hypothesis. Activity as found in hypnosis can be found in normal waking states as well. It seems to be the case, however, that during hypnosis, the executive regions that are implicated in the DMN and said to control attention, planning, volition, and behavioral flexibility, do not consolidate such subsystem activation.

A Note on Neuroimaging and EEG

With the advance of fMRI, hypnosis became one of the behaviors heavily investigated through neuroimaging. In fact, a majority of recent experiments use fMRI to examine neural correlates of hypnosis. Sometimes, fMRI is used in conjunction with PET or EEG. Karlin and Orne (2001) described EEG in detail, as this method was the prevailing one prior to the dawn of fMRI to study hypnosis. One method in EEG is to present stimuli to a participant, which result in acute alterations in activity. These changes are termed *event-related evoked potentials*, as they correlate directly to the event that is occurring in the environment, such as an auditory or visual stimulus. To distinguish event-related potentials from noise, stimulus-related activity is subtracted from a baseline of spontaneous signal or artifacts from the EEG recording. It has been shown that highly hypnotizable participants show brain activity consistent with self-reports of hallucinations during hypnosis (Crawford, 2001). Specifically, these participants showed increased or faster positive evoked potentials and decreased or slower negative evoked potentials.

Some caveats of neuroimaging studies must be kept in mind. As Raz (2011) pointed out, there is a danger of taking neuroimaging studies on hypnosis at face value without realizing some of the limitations this technique poses. He explained that the analysis of fMRI images takes multiple steps and a lot of human judgment to arrive at conclusions. Further, fMRI images are noisy, actual signals are weak, and false or coincidental patterns are readily discovered. Careful consideration must also be applied to not commit the tempting mistake of reverse inferences. Those are inferences that extrapolate a certain mental state from the activation of a certain brain region. However, this is a dangerous undertaking, as one region can be involved in multiple tasks, and activity alone does not predict its responsibility for a certain behavior. Temporal resolution in fMRI is poor, as accumulation of the fMRI signal is incremental and takes time. However, on the upside, new techniques such as diffusion tensor imaging and transcranial stimulation that can be used in conjunction with fMRI allow for the opportunity of corroborating results through converging evidence. Further, novel imaging analysis software allows for a fine-grained examination of brain activity and considers activation patterns across individual voxels without averaging voxels together (Raz, 2011). This averaging can detect activity more easily, which may lead an experimenter to commit a type I error (i.e., concluding there is a difference between experimental conditions when there is not).

Proposal for Future Research

The psychologist Daniel Kahneman, recipient of Nobel Memorial Prize in Economic Sciences in 2002, has proposed that there are two modes of thinking, which he terms System 1 and System 2 (Kahneman, 2011). System 1 can be described as automatic, intuitive, and effortless. It is fast and outside of voluntary control, and constantly integrates and updates incoming information. System 2, on the other hand, can be described as controlled and willful. It follows rules, demands attention, requires mental effort, and is involved in complex computations. The two systems are competitive and complementing each other in a dynamic and interactive way.

Even though Kahneman does not directly relate these systems to brain correlates, it is likely that System 1 involves parietal-frontal networks that mediate implicit memory, whereas System 2 involves temporal-frontal circuits and explicit memory. Thus, areas involved in System 1 might be those that maintain short-term memory and automatic, unintentional memory processes such as primed recall and procedural memories. Areas involved in System 2 might be those that pertain to executive and attentional functions and planned decisions, as well as conscious, thought-out memory processes and semantic and episodic memories.

In hypnosis, it is possible that System 2 is initially required to direct attentional focus inward. This idea is supported by psychophysiological studies that show a requirement for increased mental effort in focused attention. Specifically, Kahneman and Beatty (1966) reported that pupillary dilation proportionally increased with the amount of effort required on a cognitive task. Such pupillary dilation is also evident during hypnotic suggestion, when the focusing of attention occurs (Rossi et al., 2008). While System 2 then maintains this state of focused attention, only System 1 is left to deal with external

stimuli, such as instructions for behavioral activity. Procedural processes thus would be easily elicited and carried out, thus exemplifying the state of suggestibility that often characterizes hypnosis. Future brain imaging research might direct efforts toward identifying the neural correlates of System 1 and System 2 and how activity changes within these systems during hypnotic suggestion.

Abstract

In its various incarnations, hypnosis is among the oldest of the clinical techniques in medicine and it has been the subject of research and theory by most major figures in psychiatry and psychology from Sigmund Freud to the present. History reveals a series of cycles of ascent and decline in popularity for hypnosis along with outlandish claims of cures balanced by serious scholarly investigation. Individuals with a variety of medical and psychological ailments have been assisted by hypnotic interventions. However, despite its seniority as a treatment modality, numerous methodological and definitional issues plague those who study this area. This article will define the topic, review some of the history and evolution of the technique, outline some of the areas in which hypnosis is thought to be an effective adjunct to clinical care, and present some of the methodological complexities and limitations in the general application of hypnosis.

Definition

This treatment technique is thought to have received its name from the English surgeon James Braid (1795–1860) who used the Greek term 'ὕπνOς' (sleep) to describe his clinical observations of the physiological state of those whom he treated with this technique. Hypnosis is the direct descendant of the seventeenth- and eighteenth-century practices then called 'Magnetism,' 'Somnambulism,' and after a charismatic healer 'Mesmerism' although its roots can be traced to the religious and healing arts of antiquity. Today practitioners of hypnosis adopt the American Psychological Association's (1993) definition of hypnosis as a "procedure wherein changes in sensations, perceptions, thoughts, feelings or behaviors are suggested."

Relevant History

Chroniclers of hypnosis (see Ellenberger, 1970; Gauld, 1992) point to the work of Franz Anton Mesmer (1734–1815) as the cornerstone for the establishment of this technique in modern medicine. Mesmer's belief that an imbalance in magnetic fluid led to disease states in humans gave rise to the ritualized application of magnets to individuals with a variety of medical and psychological problems. Not only the metal apparatus, but also certain people were thought to possess the 'animal magnetism' to restore the magnetic equilibrium and health. French government and scientific investigators who tested his work were able to dispute Mesmer's disease theory, but not the results. People continued to recover from a variety of ailments by means of suggestions (i.e., ideas) provided by charismatic individuals, and the technique soon spread throughout Europe and the USA.

Sigmund Freud (1856–1939) made his living as a young psychiatrist by treating patients, almost exclusively, with hypnosis. As a student of the famous neurologist Jean Martin Charcot (1825–93) and the physician Hippolyte Bernheim (1840–1919), he learned about the efficacy of an idea that could facilitate an action or lead to symptom relief. Freud's early technique employed suggestions to deny his patients' complaints energetically and to provide assurance and motivation for the performance of more adaptive behaviors. Freud also observed hypnotized subjects seeming to possess knowledge without realization, carrying out posthypnotic suggestions without awareness of the source, and blindly following the commands of the hypnotist. As a translator of both Charcot's and Bernheim's writings on suggestion, hysteria and hypnosis and his opportunity to witness the work of both scholars, Freud was highly familiar with hypnosis and he became convinced that there were powerful, unconscious mental forces extant in humans that influenced their behavior.

In several months of intensive study at Charcot's Salpêtrière, Freud learned that traumatic events create trance states in vulnerable patients that appeared similar to those created by hypnosis during clinical interview. His teachers believed that individuals vulnerable to autosuggestion trapped painful emotion in the nervous system that gave rise to psychiatric symptoms. Patients with hysteria, especially, seemed to suffer painful reminiscences of the trauma that were expressed cognitively, affectively, somatically, and behaviorally. Since they appeared to possess similar characteristics, hypnotic trance was employed to assist patients with hysteria to revisit the scene of the original trauma, reexperience the original affects for cathartic discharge and recover from their symptoms through catharsis and insight. This technique was the basis for Freud's uncovering treatment in the *Studies on Hysteria* (Breuer and Freud, 1893–1895) and hypnosis became one of the underpinnings of the theory and technique of psychoanalysis.

The power of suggestion, the influence of unconscious mental processes in humans, and the use of hypnosis to access memories were not the only contributions of hypnosis to psychoanalysis. Freud was fascinated by the question of 'influence' and what led people to follow the directions of others. He reasoned that group activity and hypnotic treatments encourage people to minimize individual interests, personal control, discernment, personality style, and so on, and it led people to develop intense emotional relationships with others for reasons that are difficult to account for objectively. Freud wrote that the rapport created between doctor and patient in hypnosis was comparable to that of tribal members for the chief and he used it as a paradigm for his

understanding of therapeutic influence and transference throughout his career.

Where Mesmer might be credited with taking hypnosis away from the exorcists and 'healers' and placing it within traditional medicine, Freud explored hypnosis for what it could offer as a psychotherapeutic technique and for what it might contribute to his model of the mind. However, his several reports that psychoanalysis began when he 'rejected' hypnosis relegated this technique to an inferior place among methods for mental health treatment. Very few of his followers would risk alloying the 'copper of suggestion with the pure gold of psychoanalysis.' Freud's efforts to distance himself and psychoanalysis from hypnosis had something of the same dampening effect as Mesmer's failure to validate magnetic theory with scientific study.

The birth of psychology and social science research techniques during the twentieth century brought new methods of inquiry into the essence and effects of hypnosis. The rise of interest in mind–body medicine also fueled clinical interest and investment in this area. Both of these developments, along with the creation of several professional journals and international societies for the study and practice of hypnosis, contributed to the continued development of this field.

Therapeutic Applications

Medicine

A technique that can alter sensations, perceptions, thoughts, feelings, and/or behavior can be especially helpful in today's medical setting (Covino and Frankel, 1999). Patients and practitioners have long experienced anecdotal reports of symptom relief from something that a physician said, did, or proffered. Researchers in the laboratory and clinical setting have been laboring to establish empirical support for the use of hypnosis with a variety of symptomatic complaints and to manage common emotions in the medical setting to facilitate treatment.

Most clinicians have witnessed the influence of a patient's perception on the subjective experience of pain. Where an objective physiological event almost always serves as the cause of an injury, the meaning that the person makes of the event determines the amount of suffering.

In experimental laboratories, hypnotized subjects have demonstrated an ability to tolerate electric shock, ischemic, and cold pressor pain better than their nonhypnotized peers or when they employed other pain-management strategies. A substantial body of research finds that hypnotic suggestions for analgesia, distraction, and dissociation are superior to placebo, relaxation, and cognitive interventions in the management of a variety of painful conditions. Clinical research finds success for hypnosis in the management of pain associated with surgery, cancer, reflex sympathetic dystrophy, burns, interventional radiology, angioplasty, bone marrow transplant, and colonoscopy (Patterson, 2010).

A number of experimenters have been successful at producing raucous breathing and decreased pulmonary function among a subset of asthma patients by means of suggestion alone. Whether these patients were invited to believe erroneously that they were encountering an allergen or breathing a bronchoconstricting drug, the idea alone was enough to affect their breathing adversely. Several well-designed studies have found that hypnosis training has a better impact on asthma symptoms, 'as needed' medication use, and pulmonary function tests than education, relaxation, guided imagery, and placebo inhalers. Furthermore, asthma patients who were trained to use hypnosis to manage their breathing have demonstrated a superior ability to tolerate methacholine challenge testing.

Allergists, dermatologists, and others have reported successful treatment of warts, eczema, psoriasis, and other skin conditions with hypnosis. In clinical studies, suggestions to imagine bathing in salty water, increasing warm and tingling feelings on the skin, reducing blood flow to infected areas, and general healing have assisted patients to relieve itchiness, reduce inflammation, and decrease the number and size of warts. Likewise, patients with severe burns have been able to refrain from scratching, tolerate dressing changes, and reduce their use of pain medications with the help of hypnosis.

Patients with irritable bowel syndrome experience emotional distress in the form of anxiety and anger that adversely impacts gastric secretion, motility, and pain. A considerable number of these patients find relief from placebo interventions and several studies report alterations in gut physiology with hypnosis. Gastric acid secretion, gut motility, bowel habits, abdominal distention, and abdominal pain have been reported to improve with very brief hypnotic interventions aimed at increasing relaxation, controlling smooth muscle and gut activity, and bowel function.

Hypnotic training has been found to diminish the severity and frequency of bleeding episodes among patients with hemophilia. Training a small sample of patients to use hypnosis for relaxation and anxiety reduction has controlled factor usage, spontaneous bleeding and the need for transfusion. In addition, preoperative training in self-hypnosis for the control of anxiety and bleeding has been found to reduce the number of blood transfusions required by surgical patients.

One of the most common causes of noncompliance with chemotherapy among cancer patients is the significant distress that they experience from the associated nausea and vomiting. Antiemetic drugs often have their own side effects and are typically ineffective with the anticipatory emesis that is often a conditioned response. General anesthesia, also, commonly causes postoperative nausea and vomiting among surgical patients. Well-designed clinical interventions have found support for hypnosis training over relaxation techniques, distraction or individual counseling in the management of nausea and the frequency and intensity of emesis. This has been the case for pediatric as well as adult cancer patients.

Numerous methodological difficulties limit confidence and widespread application of hypnotic techniques in medicine, however, there is a substantive body of research to support its efficacy in pain relief (Montgomery et al., 2000; Patterson, 2010). As with most clinical research, the heterogeneity of the patients in terms of illness onset, type, course, previous treatments, comorbidity and so on, limits what can be said with confidence regarding the use of hypnosis in medicine. Also, many experimenters fail to include an adequate description of hypnosis, or might include hypnotic interventions as a component of more complex psychosocial interventions, or

fail to ascertain whether the subject was indeed hypnotized during the test. Nonetheless, qualified empirical evidence exists to support the efficacy of hypnotic techniques in the treatment of pain, asthma, dermatological disorders, irritable bowel syndrome, hemophilia, and hyperemesis (Pinnell and Covino, 2000). Furthermore, the use of hypnosis for certain surgical patients shortens operating time and increases speed of recovery (Lang and Rosen, 2002).

Psychotherapy

The addition of hypnosis to cognitive–behavioral treatments for anxiety disorders improves the effect of traditional psychotherapeutic interventions. The ability to alter perception, adjust expectations, increase motivation, and imagine more adaptive behaviors facilitates change, especially among those suffering from anxiety disorders. Where it was once thought that autonomic nervous system hyperarousal was the result of so-called stressful life events, recent research highlights the importance of cognitive processes such as perception. One person's strain might well be another's relief, depending upon the meaning that is made of the situation. An invitation from the hypnotist to perceive an event in a more benign fashion creates the opportunity for emotional relief and more adaptive behavior. Imaginative individuals can, also, use their capacity to picture frightening situations more vividly to expose themselves to feared stimuli successfully. These patients are able to achieve some of the same mastery as '*in vivo* exposure' without the time and travel. Behaviors can be mentally rehearsed, problems anticipated, and resolved with the help of suggestion, focused concentration and imagery. Likewise, unique motivational ideas can be the object of attention without distraction or criticism, and used to provide significant force for behavioral change.

Most efforts to use hypnosis for smoking cessation and weight control have seen modest results at best. Patients often report achieving relaxation and satisfaction with the technique, but pounds lost have been few and smoking abstinence is rarely achieved by more than a few program participants. This might well be due to the manner in which suggestions are employed to motivate patients and reduce appetite and desire. Much more is known these days about the complex manner in which patients cycle through processes of habit change as well as the benefits of medication support. Further work in this area would do well to integrate differing hypnotic approaches into the diverse phases and processes that people use in making habit change happen.

A number of clinicians have advocated the use of hypnosis for patients in psychotherapy. The hope in this area is to assist people to recover memories of difficult experiences as well as to teach a coping mechanism for managing extreme anxiety and dissociative symptoms. These therapists propose that the absorption, dissociation, and intensity of emotions that often accompanies hypnotic trance are similar to the experiences of many victims of trauma. In a manner similar to state-dependent learning, and in much the same way that Charcot and Freud employed this technique, patients are invited to experience hypnosis, revisit the initial trauma, and have an opportunity to express, integrate, and control their associated emotions. In addition, those who spontaneously experience dissociative states are taught to enter into a hypnotic trance to reduce anxiety and to achieve some ability to terminate or control hyperarousal.

In a fashion that mirrors Freud's later work, the use of hypnosis as a psychotherapeutic technique is the focus of considerable controversy. In general, as was the case with Freud, the main idea of memory recovery sits in the context of credibility and veridicality. For some patients and practitioners, it is painful and angering to raise the issue of truth in memory, since so many of those who were physically and sexually abused in their youth were frightened into secrecy. Yet, Freud seemed to see the inevitable intertwining of suggestion with dissociation in hypnosis as limiting the utility of this technique in psychotherapy.

Laboratory research finds that some modest gains in memory can be achieved from efforts to recall, especially, when these are made proximate to the experience. Cues, reviews, relaxation, and other motivational techniques also seem to aid the recovery of memory. Nonetheless, hypnotic techniques have generally failed to improve recall of word lists and eyewitness reports. On the other hand, mounting evidence suggests that people in clinical and experimental situations can be lead to the erroneous belief that an event or an experience did indeed occur. The fact that these circumstances are more likely to take place in situations of heightened emotionality, uncertainty, and unfamiliarity makes many clinicians cautious about using hypnosis as an 'uncovering' technique. Furthermore, the research evidence that exposure to hypnosis can both distort memory and increase subjects' confidence in erroneous memories has led courts of law to bar testimony obtained through the use of hypnosis.

Essential Elements and Putative Mechanisms

Despite its long history as a psychological intervention, it is not yet possible to define the mechanism of action of hypnosis. With increased access to sophisticated neuroimaging tools, there is enthusiasm for research that might define the brain mechanisms that facilitate hypnotic phenomena (Raz and Shapiro, 2002). However these studies have, thus far, failed to identify a specific neurological marker or neurophysiological substrate for hypnosis. There are, however, several ways that the beneficial effects of hypnosis have been understood.

Suggestions are ideas presented to a subject for uncritical acceptance. In hypnosis, the subject is asked to concentrate on these ideas in a manner that diminishes distraction, lessens logical analysis and maximizes acceptance and acquiesce. Suggestions are not commands, but invitations that can be rejected or accepted. However, like the response of patients to placebo medications, there is often a sense of involuntariness to hypnotic responses and an attribution of causation to the hypnotist. The physical context, psychological expectations, or the pressure to fit in well with a group can also provide direction for a person's thoughts, feelings, or behaviors. Some theorists maintain that these psychosocial factors alone or in combination result in successful hypnotic response.

The ability to become absorbed in an idea as if it is real and to use fantasy and imagery to alter cognition and/or behavior is

also seen as a determinant of successful hypnotic response. Such special concentration is thought to invite a state of dissociation where consciousness is divided. The ability to separate awareness of sensation, memory, time, behavior, and so forth is not only part of daily experience (e.g., shifting the gears of a car without awareness, daydreaming), but it can be created by hypnotists and imaginative patients. Such ability is thought to facilitate the use of hypnosis in management of painful conditions and anxiety. Since the higher cognitive faculties are blocked from elaborating pain or anxiety signals, emotional or behavioral responses are muted or stopped.

There are a number of clinical, and perhaps nonspecific, factors that facilitate or hinder the response of patients to hypnosis. Patients must be motivated to follow the suggestions of the hypnotist. A fearful, overly defensive, unwilling person will rarely succeed with hypnosis and one who feels safe, valued, and cared for by an 'expert' most likely will. Research indicates that hypnotizability appears to be a rather normally distributed, stable, trait. Although there are some that claim that anyone can achieve some benefit from hypnotic interventions, many hypnosis experts find that those with heightened ability are the most helped. Certain conditions favor suggestion such as ambiguity, uncertainty, novelty, and hyperemotionality. Good hypnotic technique endeavors to recruit or develop some of these elements.

Abstract

The Hypothalamic-pituitary-adrenal axis (HPA axis) has been shown to play a major role in the regulation of a variety of physiological as well as psychological processes. This article will give an overview over its structure and its diverse functions, such as basic bodily functioning, behavior, stress reactions or psychopathology. Furthermore, the underlying mechanisms as well as the diverse internal and external parameters which modulate basal HPA axis activity and reactivity as well those processes associated with HPA axis activity will be discussed.

The Hypothalamic-Pituitary-Adrenal Axis: Basic Concepts and Regulation

The hypothalamic-pituitary-adrenal axis (HPA axis) has been shown to play a major role in the regulation of a variety of physiological as well as psychological processes, most prominent among them being the stress reaction. Its primary effector-hormone in humans, cortisol, released from the adrenal cortex, is considered one of the major stress hormones. The HPA axis constitutes a closely regulated hormonal axis, which plays a critical role in maintaining homeostases and shows a high reactivity to internal as well as external stimuli.

On activation through a variety of stimuli, the paraventricular nucleus (PVN) within the hypothalamus secretes corticotropin-releasing hormone (CRH) and arginine-vasopressin (AVP) into the hypophyseal portal vein. CRH constitutes the major stimulus for the anterior pituitary to produce and secrete adrenocorticotropic hormone (ACTH) into the general circulation. AVP works in synergy with CRH in stimulating ACTH release. ACTH then stimulates glucocorticoid (GC) secretion, with cortisol being the primary GC in humans, and to a lesser degree mineralocorticoid (mainly aldosterone) secretion from the adrenal cortices (see Figure 1). The HPA axis is closely regulated through negative feedback loops; i.e., circulating GCs participate in their own regulation by inhibiting ACTH production in the pituitary as well as CRH production in the hypothalamus (see Figure 1).

Under normal resting conditions – that is in the absence of stressful stimuli – the release of CRH and AVP occurs in a pulsatile fashion and follows a clear circadian rhythm, which also is reflected in the rhythmic release of cortisol. This circadian rhythm is ultimately under the control of the suprachiasmatic nucleus (SCN, the primary endogenous pacemaker), via its connections to the PVN. In humans, cortisol levels throughout the day are characterized by showing the lowest levels around midnight, followed by a steady rise until awakening and reaching a peak within the first 30–60 min after awakening (cortisol awakening response). Levels continuously decline over the course of the day and finally reach the nadir again during sleep. This circadian rhythmicity may, however, be modulated by changes in internal or external conditions, such as time of food intake, light conditions and timing, shift work or activity status (e.g., physical activity like sports will increase cortisol levels); it is disrupted by stress. During acute stress reactions, CRH and AVP release is massively increased, resulting in augmented production of ACTH as well as GCs in turn, which are pivotal in allowing an adequate adaption process to stress. Cortisol increase in response to a stressor is comparably slow in healthy humans, starting approximately 10 min after onset of stress and being downregulated to baseline levels within the first hour after cessation of the stressor. GC release magnitude in healthy individuals, however, is limited by hormonal as well as neural mechanisms, as hyperproduction of GCs is involved in a variety of severely negative health-outcomes (see below for details). Animal models as well as studies in humans indicate that resilience to stress is associated with a rather rapid activation of the stress response plus its efficient deactivation; i.e., a close and effective control of HPA axis activity in the form of termination of GC release via negative feedback loops. A further important point to keep in

Figure 1 Simplified, schematic view of HPA axis. For details, please refer to the text; CRH: corticotropin-releasing hormone, AVP: vasopressin, ACTH: adrenocorticotropic hormone, GC: glucocorticoids, MC: mineralocorticoids.

mind when analyzing GCs and their psychobiological relevance is that a high proportion of serum GCs is bound to proteins and therefore biologically inactive. In humans, approximately 90% of plasma cortisol is bound to corticosteroid-binding globulin (CBG) and a further 7% to serum albumin, leaving only *c*. 3% free and therefore biologically active.

The effects of GCs are facilitated via the glucocorticoid receptor (GR), type II, and the mineralocorticoid receptor (MR), type I. Both receptors are part of the steroid receptor family; i.e., they constitute ligand-dependent transcription factors. Both are localized within the cytoplasm. Upon hormone binding, the receptor–hormone complex enters the nucleus and acts as a transcription factor on specific target sites in the genome – i.e., it is able to modulate gene transcription. Beyond these genomic effects, more rapid nongenomic effects have been described. These are thought to play an important role in coordinating a rapid adaptive response to stress. The mechanisms, however, by which this rapid nongenomic signaling is achieved are not fully understood (for review, see Groeneweg et al., 2012). GRs are found to be distributed widely throughout the mammalian central nervous system, most notably in the hypothalamus and the pituitary gland but also in parts of the limbic system such as the amygdala and hippocampus. MRs seem to be somewhat more restricted in their anatomical localization, having been shown in limbic structures; i.e., predominantly in the hippocampus but also in the amygdala.

HPA axis activity is controlled by a multitude of afferents that are thought to coordinate HPA axis activity status with internal and external stimuli. Of note, there appear to be different neural pathways that respond to different stimuli activating the PVN neurons and triggering HPA axis activation. From the brainstem pathways project directly into neurons of the PVN, with catecholamines promoting HPA axis activation in response to hemorrhage, respiratory disease, hypotension and potentially immune challenge as well. As mentioned above, the SCN takes part in controlling circadian rhythmicity via connections to the PVN. Further activational input might derive from connections to the amygdala, which is known to elicit stress responses and also plays a pivotal role in emotional regulation. Another limbic structure might also excite HPA axis activity: the bed nucleus of stria terminalis , which is involved in controlling basic homeostatic processes. Beyond direct limbic pathways, aminergic inputs from both the locus caeruleus, the main CNS site producing noradrenaline , as well as the raphe nuclei, which produce the monoamine serotonin (5-HT), may activate the HPA axis as well. Since direct neural pathways to the HPA from both systems are comparably limited, however, it is thought that more indirect pathways – e.g., through the more numerous innervations of limbic areas – are at work as well. (see Herman and Cullinan, 1997 for details).

HPA Axis: Diverse Functions and Clinical Correlates – A Short Overview

The effector hormones of the HPA axis, GCs and mineralocorticoids, play a role in the regulation of a variety of basic physiological functions and processes, such as carbohydrate metabolism, protein metabolism, fat metabolism, sleep, connective tissue, the hematopoietic system, the cardiovascular system, speed of signal transduction in the central nervous system, water and electrolyte balance and immune system activity. The proper functionality of the HPA axis is pivotal for maintaining bodily functions under normal conditions, keeping up homeostases and, thereby, health of the individual.

These diverse functions are also reflected in the variety of symptoms which might be caused in case of dysregulation of HPA axis activity. For example, hypercortisolism (also referred to as Cushing syndrome), which might be caused by exogenous factors, such as systemic administration of ACTH or corticoids during treatment of autoimmune diseases or allergies. Alternatively, it can also be caused by an increased production of ACTH in the pituitary, which results in increased corticoid production in turn (central Cushing syndrome). Adrenal Cushing's disease is characterized by an increased production of corticoids from the adrenal glands caused by neoplasia (adenomas or carcinomas), which is accompanied by an inhibition of ACTH release due to increased negative feedback-loop activation. Symptoms of hypercortisolism are diverse and often severe, underlining the relevance of HPA axis functioning, especially the need to closely regulate levels of fluctuating GC in the body (see Table 1). However, not only increased levels of cortisol are detrimental to health, this is also true for hypocortisolism which also has severe negative effects on one's health (see Table 1).

Furthermore, dysregulation of HPA axis activity has been shown to play a role in the etiology of several psychopathological conditions such as depression, burn-out syndrome, anxiety disorders, posttraumatic stress disorder (PTSD), borderline personality disorder, anorexia nervosa, schizophrenia or bipolar disorder. Of the variety of HPA axis-associated psychopathological conditions, depression probably is the most widely studied. Patients have been shown to exhibit marked changes in HPA axis activity as well as its regulation; Circadian rhythm of cortisol is often disturbed, hyperfunctionality of HPA axis and accompanying increased cortisol levels have been shown and the ability to down-regulate HPA-axis activity to baseline levels after exposition to a stressor additionally appears to be disrupted. In about 50–60% of patients suffering from acute clinical depression, such changes in HPA axis regulation might be found. Furthermore, successful antidepressant treatment is able to normalize these dysregulations. Interestingly, however, HPA axis activity is not fully normalized in all patients. This lack of normalization is a clinical indicator of the risk of relapse in patients. Today it is believed that the abnormal functionality of the HPA axis is one of the key pathological mechanisms in depression. In this context, cognitive impairments, which often accompany depression, are of interest as well. For one thing, they can be used as predictors of outcome of antidepressant therapy as well as risk of relapse. Furthermore, they often persist even when psychopathological symptoms are relieved. This lead to the assumption that these cognitive impairments are caused by changes in functional networks involved in the etiology of depression, which is further

Table 1 Hyper- and hypo-cortisolism: symptom overview

Hypercortisolism (Cushing's disease)
Obesity of the upper body
Thin arms and legs
Moon-mace (round, red, full face)
Acne or skin infections
Purple marks (1/2 inch or more wide), called striae, on the skin of the abdomen, thighs and breasts
Thin skin with easy bruising
Backache which occurs with routine activities
Bone pain or tenderness
Collection of fat between the shoulders (buffalo hump)
Thinning of the bones, which leads to rib and spine fractures
Weak muscles
Fatigue
Headache
Increased thirst and urination
Reduced sexual desire
Diabetes mellitus, type II
Mental changes, such as depression, anxiety or changes in behavior
In women: Excess hair-growth on the face, neck, chest, abdomen and thighs, and menstrual cycle that becomes irregular or stops
In men: erectile dysfunction
In children: reduced growth rate
Hypocortisolism (Addison's disease)
Muscle weakness
Muscle pain
Joint pain
Fatigue/weakness
Loss of appetite
Weight loss
Cravings for salt
Low blood pressure
Low blood sugar
Darkening skin
Changes in mood, depression and irritability, being emotionally hypersensitive
Diarrhea
Shakiness
Body aches
Sensitive skin
Nausea
Vomiting
Hypoglycemia

underlined by findings that show hypercortisolism to be associated with impaired cognitive functioning, especially memory deficits. One underlying mechanism appears to be hippocampal volume reduction, which is thought to be caused by chronically increased circulating GCs. These do not only cause atrophy of hippocampal neurons, but also inhibit long-term potentiation. Several lines of evidence suggest that these effects are mostly mediated by GRs.

Given the wide variety of health and disease related processes the HPA axis is involved in, it is not surprising that a wide body of research was concerned with finding those factors which determine HPA axis basal activity as well as reactivity. A major focus of research regarding the HPA axis and its psychobiological correlates has therefore been into individual differences in stress reactivity and associated psychopathological states. By now, several sources of individual differences in HPA functioning have been identified and will be discussed in the following paragraphs.

HPA Axis: Determinants of Individual Differences in Functioning

Interactions with Other Hormone- and Neurotransmitter Systems

When trying to understand the determinants of individual differences in HPA axis functionality, one has to keep in mind that the HPA does not act independently from other neuroendocrine systems. Indeed, it has been shown that HPA axis basal activity as well as reactivity is modulated by and itself modulates the activity of a variety of other hormone- and neurotransmitter systems, such as 5-HT, dopamine, noradrenalin, sex steroids, oxytocin and vasopressin or growth hormone. Therefore, a certain percentage of individual differences in HPA axis functioning must to attributable to the complex interactions with other systems.

A well-studied example of such complex interplay between systems is the bidirectional functional connectivity between the HPA axis and the sex steroids, the neuroendocrine basis of the reproductive system. GCs might inhibit sex steroid activity in multiple levels: by inhibiting the release of (1) gonadotropin-releasing hormone in the hypothalamus, (2) the *pituitary gonadotropins*, or (3) the gonads. Furthermore, GCs might cause a resistance to sex steroids in their target tissues. Within subjects exhibiting chronic HPA axis activation (e.g., patients with anorexia nervosa or competitive athletes) suppression of gonad activity has been shown, i.e., GCs do not only modulate sex steroid activity, but the sex steroids might modulate HPA axis activity as well. Estrogen response elements, for example, have been found in the promoter region of the CRH gene, indicating that estradiol might modulate CRH expression via its genomic effects. This is further supported by the fact that a direct stimulation of CRH gene expression has been shown. These and other results are thought to play a role in the underlying mechanisms of the well described sex-differences in HPA axis activity.

Growth hormone release has been demonstrated to be inhibited by prolonged HPA axis activation from stress. Interestingly, however, with the onset of a stressor growth hormone levels actually might be temporarily increased. This increase is thought to be mediated via the genomic effects of GCs, which bind at GC response elements localized in the promoter region of the growth hormone gene.

The peptide hormone oxytocin, which has been implicated in the regulation of social behaviors as well as emotion regulation and is thought, inter alia, to possess anxiolytic and stress-reducing properties has been shown to interact with HPA axis functionality. Oxytocin might reduce HPA axis responsivity to stress, and is thought that the stress buffering effect of social support is mediated via oxytocin and its ability to attenuate HPA axis stress reactivity. In humans, for example, intranasal application of oxytocin reduces cortisol responses during couple conflict. Interestingly, social support during a psychosocial stress situation as such is able to reduce not only subjective negative affective responses to stress but also cortisol

release; an effect which is even more pronounced after intranasal application of oxytocin.

Effects of Adverse Environmental Factors

A further source of variance in basal HPA axis activity as well as reactivity appears to be adverse environmental stimuli, especially experiences during early life.

The adverse effects of wearing circumstances of life or stressful minor and major life events on indicators of psychological and physical health have been shown repeatedly. As summarized in several review articles, a clear association has been shown between adverse environmental conditions and the occurrence as well as progression of several somatic (e.g., delayed wound healing, inflammatory disease, tinnitus, multiple sclerosis, coronary heart disease and others), somatoform as well as psychological illnesses (e.g., affective disorders, PTSD and others) (McEwen, 2006; Nater et al., 2006).

One underlying mechanism thought to play a role in explaining the detrimental effects of stress on physiological as well as psychological health, especially severe stressors experienced during early phases of development, is stress-induced abnormal functioning of the CNS; inter alia dysregulation of HPA axis basal activity as well as reactivity. Indeed, the acute stress burden of any given persons – e.g., problems related to work or family, chronic illness etc. – appears to modulate acute activity of the HPA axis. It has been shown that chronic stress might change the normal circadian rhythm of cortisol; i.e., is characterized by elevated basal cortisol levels. Furthermore, the neuroendocrine acute stress response appears to be reduced, and recovery times are augmented; i.e., downregulation of cortisol levels to baseline levels.

The effects of early stressful or traumatic environmental conditions, however, appear to be far more important, as they are often found to be associated with lifelong maladaptive changes in HPA axis regulation. A number of studies show that stressful experiences, especially during early life, might have long-lasting effects on HPA axis activity. For example, children who were subject to long-term separation from parents or lost their parents to death have been shown to exhibit reduced basal cortisol levels, nonresponsivity in the dexamethasone suppression test (indicating a dysfunctional feedback regulation of the HPA axis) as well as a hyperactive HPA axis. Further support for the assumption that stressful environmental stimuli might cause changes in HPA axis function stem from numerous studies in patients suffering from different forms of anxiety disorders (inter alia, posttraumatic stress disorder , panic disorder or social phobia) and with a history of a variety of early life stressors, who exhibit marked alterations in HPA axis activity; e.g., alterations in cortisol response to stress or changes in basal activity of CRH or abnormal reactions to the dexamethasone suppression test (for review, see Faravelli et al., 2012). Similar results have been shown in numerous animal studies, further underlying the strong adverse effects early life stress might have on HPA functionality. For example, rhesus macaques which have been reared in separation from their mothers, show substantially increased neuroendocrine stress responses when compared with mother-reared animals. These results are further supported by separation experiments in rodents. Particular noteworthy in the context of animal studies are those showing how HPA axis activity and its downstream effects on behavior as well as personality might be modulated by epigenetic changes caused by early environmental stimuli. In this context, a study on rats was able to demonstrate how maternal care might have long-lasting effects on the offspring's personality, behavior as well as HPA axis functioning, which were mediated by epigenetic changes in response to a specific environmental stimulus. The offspring of naturally high-nurturing rat mothers were compared to those of low-nurturing mothers. The adult offspring of low-nurturing mothers were characterized by increased anxiety and stress sensitivity, also reflected in heightened corticosterone secretion under stressful conditions as well as increased GR expression rates in the hippocampus. Subsequent analyses showed this increase in GR expression to be mediated through an increase in methylation markers in the promoter region of the GR gene, which appear to prevent binding of the transcription factor nerve growth factor-inducible protein A and those reducing transcription rate of the GR gene.

Taken together, the data available today show early life stress to consistently be associated with marked changes in HPA axis regulation on several levels (CRH levels, feedback regulation of HPA axis as well as stress reactivity), thereby disrupting an adaptive response to stress – i.e., a rapid activation followed by an efficient termination.

Effects of Genetic Factors

It is important to keep in mind that HPA axis functionality is not only modulated by environmental stimuli, but is also partially determined by genetic factors. This means that naturally occurring variance within those genes involved in HPA axis regulation – e.g., encoding for GC and MRs, enzymes involved in GC synthesis, or regulator hormones like CRH – might be associated with changes in activity of their respective protein products and thus also with changes in HPA axis functionality.

An example of such effects is a single nucleotide polymorphism (SNP) in the GR gene (NR3C1), the Asn363Ser (rs6195, N363S, A to G transition, Codon 363 (Exon 2); the major allele encodes for asparagine, while the minor G-allele encodes for serine). Homozygote carriers of the G-allele have been found to show increased corticosteroid sensitivity as well as an augmented HPA axis reactivity to acute psychosocial stress. Furthermore, carriership of the minor allele has been associated with higher waist-to-hip ratio, higher body-mass index (BMI) as well as increased insulin secretion after dexamethasone intake. These associations reflect changes in metabolic activity that are at least partially under HPA axis control. The critical minor allele appears to increase cortisol reactions to stress, this in turn is thought to cause a bodywide overexposition with cortisol, which itself is associated with several adverse metabolic effects. Another SNP within the GR gene which appears to modulate GR receptor sensitivity is the Bcl-1 (rs41423247, C > G, 647 base pairs downstream of exon 2). Again, the SNP has been shown to be associated with GC hypersensitivity as well as associated metabolic changes. Regarding cortisol reactions to an acute stressor, results are less clear, whereby some data indicate that homozygosity for the minor allele is associated with reduced cortisol reactions.

However, this association appears to be further modulated by gender, with women showing increased cortisol reactions and men reduced levels of cortisol.

The MR is another important protein involved in regulating HPA axis activity. Within its gene (NR3C2) a functional SNP, I180V (rs5522, a missense SNP, isoleucine–valine), has been described, which is associated with increased physiological stress reactivity; i.e., cortisol as well as heart rate and also increased emotional reactivity.

A further well-studied example for the relevance of genetic variance in determining HPA axis activity is an SNP within the FKBP5 gene, which encodes a protein taking part in modulating GR sensitivity as a cochaperone. When FKBP5 binds the GR it attenuates GR affinity for cortisol, which is also accompanied by a reduction in the amount of active GR translocated to the nucleus. Several SNPs within this gene have been identified and studied with respect to their associations with stress sensitivity as well as HPA functionality. The rs1360780 (C/T) has given rise to the most consistent findings. The T-allele is associated with increased FKBP5 expression, which in turn is associated with relative GR resistances. Furthermore, TT-homozygote subjects show a substantially slower endocrine stress-recovery; i.e., downregulation of cortisol after exposure to a psychosocial stress is significantly slower as when compared with C-allele carriers. These results were further corroborated in infants exposed to a stressor, with T-allele carriers showing increased cortisol responses. This SNP might also modulate antidepressant-response in patients, with TT-homozygotes exhibiting more depressive episodes, but also showing a better response to treatment.

In line with the complex interactions with other hormone and transmitter systems described above, genetic variance within genes encoding regulatory proteins of those systems have been shown to be associated with changes in HPA axis functionality as well. Widely studied examples include genetic indicators of serotonergic (e.g., the 5-HTTLPR) or dopaminergic activity (e.g., the COMT val^{158}met polymorphism) or brain-derived neurotropic factor (BDNF); e.g., the BDNF val^{66}met polymorphism. A more detailed summary of genetic markers implemented in regulation of stress reactivity and HPA axis functioning might be found in suitable reviews (see references, e.g., Stephens and Wand, 2012; DeRijk and de Kloet, 2005; Derijk and de Kloet, 2008; Feder et al., 2009).

Importantly, the associations regarding the different genetic variants described above by the way of examples were not replicate in all studies, and further research is needed to understand the exact mechanisms involved in order to explain these discrepancies (e.g., DeRijk and de Kloet, 2005; Luijk et al., 2010). One particularly promising approach to explain the often inconsistent results of molecular–genetic association studies, such as described above, are gene × environment interactions – i.e., persons with different genotypes reacting differently to the same environmental stressor. The following paragraph will give a short summary of chosen aspects regarding gene × environment interactions and their relevance for HPA axis activity.

Gene × Environment Interactions

By now, several studies have shown the high relevance of gene × environment interactions in explaining HPA axis basal activity as well as stress reactivity. Furthermore, there are several examples which show how individual differences in facets of trait personality (e.g., neuroticism or anxiety) which have been shown to be associated with coping abilities as well as affective and neuroendocrine aspects of stress-sensitivity also might be explained in terms of gene × environment interactions.

A prominent and well-studied example within this line of research are genetic predictors of serotonin system activity, due to the high relevance of serotonin in affect regulation and stress reactivity (Ressler and Nemeroff, 2000; Nugent et al., 2011). Regarding stress sensitivity, one of the most widely studied genetic factors is the serotonin transporter-linked polymorphic region (5-HTTLPR), a functional polymorphism in the promoter region of the serotonin reuptake transporter gene. Several studies came to the conclusion that carrying an s-allele of the 5-HTTLPR constitutes a genetic sensitivity factor toward adverse/stressful environmental factors, which reduces one's capacity to adaptively cope with stressors (for review, see Caspi et al., 2010). Moreover, a direct link between this increased sensitivity and the etiology of psychopathology (especially affective disorders) or intermediate phenotypes (e.g., increased reactivity toward negative affective stimuli, amygdala reactivity or dysregulation of stress hormones) has been demonstrated (for review, see Caspi et al., 2010). Accordingly, many authors interpret the s-allele in the sense of a genetic vulnerability factor. These results, however, are somewhat controversial, and the question, whether or not the 5-HTTLPR does constitute a modulator between adverse environmental factors and associated negative outcomes, is still discussed rather critically. Therefore, the question was raised whether the s-allele is associated with an overall increased reactivity to environmental stimuli, regardless of their valence (Belsky and Pluess, 2009). Thus, s-allele carriers would be more vulnerable to the negative effects of stressful LEs, but would also benefit disproportionally from positive environmental influences. This notion is supported by several studies indicating that the s-allele might not be a genetic risk factor, but rather constitutes a genetic plasticity factor associated with increased reactivity to environmental stimuli regardless of their valence, thereby modulating personality facets such as neuroticism, which in turn is associated with stress reactivity.

Several further examples underline how dispositional genetic factors interact with environmental conditions in shaping the activity of the HPA as well as stress responsivity. For example, the previously discussed polymorphism within the FKBP5-gene, rs1360780, does not only show direct associations with cortisol reactivity. Rather, these effects are further dependent on environmental stimuli. In a study on the influence of parent – infant attachment relationship on the regulation of HPA axis activity, it was found that in infants the combination of being a T-allele carrier plus having an insecure attachment relationship with the mother resulted in a doubled risk for increased cortisol relations to stress. Regarding the FKBP5-gene, evidence has been found that several SNPs and haplotypes described modulate the association between childhood trauma and PTSD, depression as well as suicide (Luijk et al., 2010).

Similar gene × environment interactions have been shown for genetic variations of the corticotropin-releasing hormone

receptor (CRH1) gene which interact with early life stress to predict adult depression. Furthermore, the association between childhood maltreatment and HPA axis activity, as measured with the dexamethasone/CRH test, was modulated by SNPs within this gene. The authors concluded that this excessive HPA axis activation might be the underlying mechanism of the interaction of genetic risk factors and the etiology of stress-associated diseases such as mood or anxiety disorders (Tyrka et al., 2009).

A vast amount of literature further underlining the complex interplay between genetic and environmental factors in shaping HPA axis might be found in suitable reviews (see reference list).

In conclusion, it is by now apparent that the HPA axis and its psychological, behavioral and physiological correlates are subject to regulation and modification by a complex and widespread network of different inputs, which are of high relevance for physical as well as psychological health.

Abstract

Although only a small part of the vertebrate brain, the hypothalamus has a key regulatory function. Being primarily involved in the regulation and maintenance of internal homeostases of several vital bodily functions and neuroendocrine rhythmicity, the hypothalamus adapts bodily functions to internal and external changes as required, thus being a vital component in the body's ability to adapt to internal and external stressors. It is closely linked to the largest intracranial endocrine gland, the pituitary or hypophysis, through which it controls a majority of other endocrine systems.

The hypothalamus is an integral part of the vertebrate brain. Its key function is one of regulating and maintaining internal homeostases as well as neuroendocrine rhythmicity. It does so by directly controlling the vegetative nervous system, major parts of the endocrine system and even basal behavior. The hypothalamus is a part of the diencephalon ('interbrain'), consists mainly of gray matter – the hypothalamic nuclei – and makes up for less than 1% of total brain volume. It is strongly associated with and directly controls the pituitary; an amalgam of various endocrine cells of ectodermal origin (anterior lobe) as well as peptide-hormone releasing hypothalamic axons (posterior lobe).

Ontogeny

Hypothalamus

Around the sixth week of gestation the diencephalic bubble develops four distinct layers. These are, from dorsal to ventral, the epithalamus, the dorsal thalamus (i.e., the thalamus proper), the ventral thalamus (which develops into the pallidum, the reticular nucleus of the thalamus, the subthalamic nucleus and the zona incerta) and the hypothalamus. At this stage of ontogeny the epithalamus has already developed an anlage for the pineal gland, and the hypothalamus shows a frontal anlage for the infundibulum (hypophysial stalk) and an occipital anlage for the mammillary bodies. The infundibular anlage develops into the neurohypophysis (posterior lobe of the pituitary gland) and the median eminence. The relative abundance of embryonic testosterone in relation to maternal and embryonic estrogens leads to early sex-differences in the development of individual hypothalamic nuclei, wherefore the hypothalamus can be considered as a highly sexually dimorphic part of the brain. During the later stages of embryonic ontogeny the fibers of the optic tract begin to form the optic chiasm frontally of the infundibular anlage. The disproportionate growth of the dorsal thalamus leads to a displacement of the diencephalic subsections, whereby the epithalamus is displaced caudally, the ventral thalamus in major parts is displaced laterally and the hypothalamus begins to form a cone-like shape projecting toward the sella turcica at the base of the skull. The hypothalamus itself develops from progenitor cells that migrate outward and first form the lateral and posterior hypothalamic zone, second, the intermediate zone or hypothalamic core and last, the periventricular or midline zone. This fashion of development is phylogenetically highly conserved.

Pituitary Gland

Around the fourth week of gestation ectodermal epithelial cells from Rathke's pouch (an embryonic depression in the roof of the mouth) ascend and contact the infundibular anlage, which by the same time has emerged as a downgrowth from the diencephalic neuroepithelium. By the sixth week, Rathke's pouch has completely disassociated from the oral epithelium; its dorsal aspect develops into the intermediate part of the pituitary, while its ventral aspect proliferates considerably and forms the anterior lobe of the pituitary, aka the adenohypophysis. The neuroepithelial cells of the infundibular anlage induce the development of Rathke's pouch as well as attract it to ascend toward themselves. Afterward, around the third month of gestation, they develop into pituitary-specific glial cells (pituicytes). Around the same time, nonmyelinated axons from the supraoptic and paraventricular nuclei of the hypothalamus (SON and PVN, respectively) grow into the developing glial tissue and form regular varicosities (Herring bodies) for the release of the neurohypophyseal hormones, antidiuretic hormone (ADH) and oxytocin. Immunolabeling-studies show the production of adenohypophyseal hormones starts around the 7th–12th week of gestation, that of the hormones of the posterior pituitary around the 12th–14th week. Interestingly, however, the production of hypothalamic hormones for the control of the anterior pituitary as well as the development of hypophyseal portal vessels to transport said hormones develop several weeks later. Even though the anlages of the hypothalamic–pituitary axis (HP-axis) develop relatively early during ontogeny, its maturation is not completed until way after parturition.

Morphology, Organization and Localization within the Developed Human Brain

The hypothalamus is bordered medially by the third ventricle, dorsally by the mesencephalic tegmentum and apically by the

Table 1 Overview of the major hypothalamic nuclei

	Lateral zone	*Intermediate/medial zone*	*Midline/periventricular zone*
Preoptic region	Lateral preoptic area (LPA)	Medial preoptic nucleus (MPN)	Periventricular preoptic nucleus (PPN)
Anterior region	Supraoptic nucleus (SON)	Paraventricular nucleus (PVN), anterior hypothalamic nucleus (AHN)	Suprachiasmatic nucleus (SCN), paraventricular nucleus (PVN)
Tuberal region	Lateral hypothalamic area (LHA), tuberomammillary nucleus (TMN)	Ventromedial nucleus (VMN), dorsomedial nucleus (DMN), tuberomammillary nucleus (TMN)	Infundibular/arcuate nucleus (IAN)
Mammillary region		Posterior hypothalamic nucleus (PHN), dorsal & ventral premammillary nuclei (DPM; VPM), medial and lateral mammillary nuclei (MMN; LMN), tuberomammillary nucleus (TMN)

Figure 1 Hypothalamus. Modified from Paulsen, F., Waschke, J. (Eds.), 2010. Sobotta: Atlas der Anatomie des Menschen – Kopf, Hals und Neuroanatomie. Elsevier, Munich.

hypothalamic sulcus. The base of the hypothalamus is the tuber cinereum, which transits laterally into the anterior perforated substance and frontally into the lamina terminalis. The tuber cinereum transitions into the infundibulum toward the sella turcica at the base of the skull, which contains the pituitary. Occipitally, on both sides of the midline, the tuber cinereum borders on the two mammillary bodies.

Apart from the aforementioned distinction between the longitudinally oriented lateral, intermediate and midline zones, the hypothalamus can be divided from rostral to occipital in a coronal fashion into the preoptic, anterior, tuberal and mammillary regions. The distinct hypothalamic nuclei can therefore be grouped within a three-by-four continuum (q.v., Table 1 and Figure 1).

Connections of the Hypothalamus

Pituitary Gland

As described above, the major endocrine output pathway of the hypothalamus is via the pituitary gland, which is connected to the hypothalamus in two distinct fashions. The anterior pituitary, consisting of endocrine cells of ectodermal origin, is connected with and controlled by the hypothalamus via the hypophyseal portal vein. Nuclei of the hypothalamus (mainly the tuberal and infundibular/arcuate nuclei) produce releasing and inhibiting hormones, which are secreted into the portal system and stimulate or inhibit the release of hormones from the anterior pituitary. The posterior pituitary does not, of itself, produce hormones, but consists of axons from the hypothalamic supraoptic and paraventricular nuclei, stabilized by the pituicytes. These axons form regular varicosities (Herring bodies), where the hormones antidiuretic hormone (ADH) and oxytocin are released into the bloodstream. The anterior and posterior lobes of the pituitary are separated by the intermediate part (q.v., Figure 2), and the posterior pituitary continues into the tuberal part, which connects it to the hypothalamus.

Larger magnification of the anterior pituitary reveals the presence of three histologically differently reactive cell-populations. These are the acidophilic, basophilic and chromophobic cells (q.v., Figure 3), whereby the function of the latter is not clear. It is considered that these cells could either be progenitors of either or both of the other cell types, individual cells of either or both of the other two types that have recently released their contents and therefore do not react to histological stainings and antibodies, or even a group of cells producing hormones that are currently unknown and can therefore not be stained with common antibodies.

Figure 2 Overview of the human pituitary gland sectioned in the sagittal plane. Image by Grant, taken from histological sections from the Microscopic Anatomy course of the Institute for Anatomy and Cell Biology, University of Giessen.

Acidophilic cells produce the so-called nonglandotropic hormones, which have in common that they stimulate cells that are themselves not endocrine, unlike the glandotropic hormones, which are produced in the basophilic cells and in turn stimulate further endocrine glands; i.e., the thyroid, the adrenal cortex and the gonads (testes or ovaries). The highly feedback-regulated control mechanisms of these latter three endocrine glands are therefore also referred to as the hypothalamic–pituitary–thyroid (HPT), –adrenocortical (HPA) and –gonadal (HPG) axes (q.v., Section Hypothalamic–Pituitary–Thyroid (HPT) Axis). The basophilic cells of the anterior pituitary can therefore be further divided into thyrotropic (producing thyroid-stimulating hormone [TSH], aka thyrotropin), corticotropic (producing pro-opio-melanocortic [POMC], which is posttranslationally processed into adrenocorticotropic hormone [ACTH], aka corticotropin, α-melanotropin [α-MSH] and β-endorphin) and gonadotropic cells (producing the gonadotropins [Gn] luteinizing hormone [LH] and follicle-stimulating hormone [FSH]).

Acidophilic cells can be divided into somatotropic and mammotropic cells, whereby the first produce growth hormone (GH), aka somatotropin, and the latter prolactin. Unlike the basophilic cells, which are stimulated by the hypothalamus but inhibited by the final hormone of their respective HP-axis, acidophilic cells are both stimulated and inhibited by the hypothalamus. Therefore, two hormone classes exist that bind to acidophilic cells, namely releasing and inhibiting hormones (i.e., growth hormone–releasing and –inhibiting hormone (GHRH and GHIH) as well as prolactin–releasing and –inhibiting hormone (PRH and PIH)). GHIH and PIH have been identified to be the same chemical compounds as somatotropin (produced by endocrine cells of the digestive system, especially the δ-cells of the endocrine pancreas) and dopamine (which is usually found to act as a neurotransmitter), respectively. PRH has been shown to be a confusing hormone, since it has become clear that the major factor involved in prolactin release is actually TRH; the exact functions of PRH are therefore unknown.

Figure 3 Detailed view of the endocrine cell types of the anterior pituitary (A: acidophilic cell; B: basophil cell; C: chromophobic cell). Image by Grant, taken from histological sections from the Microscopic Anatomy course of the Institute for Anatomy and Cell Biology, University of Giessen.

Table 2 Overview over the major hypothalamic hormones related to the pituitary gland

Hormone	*Main function*
Corticotropin-releasing hormone (CRH)	Stimulation of POMC/ACTH-production
Thyrotropin-releasing hormone (TRH)	Stimulation of TSH- and prolactin-production
Gonadotropin-releasing hormone (GnRH)	Stimulation of LH- and FSH-production
Growth hormone–releasing hormone (GHRH)	Stimulation of GH-production
Growth hormone–inhibiting hormone (GHIH)	Inhibition of GH-production
Prolactin-releasing hormone (PRH)	Unknown
Prolactin-inhibiting hormone (PIH)	Inhibition of prolactin-production
Antidiuretic hormone (ADH)	Increase of water-retention in the kidneys
Oxytocin	Maternal and pair-bonding, prosocial and anxiolytic effects

Table 3 Overview over the hormones of the anterior pituitary

Hormone	*Main function*
Growth hormone (GH)	Stimulation of most bodily cells
Prolactin	Stimulation of lactation, sexual gratification
Corticotropin (ACTH)	Stimulation of adrenal cortex
Thyrotropin (TSH)	Stimulation of thyroid
Luteinizing hormone (LH)	Stimulation of ovaries/testes
Follicle-stimulating hormone (FSH)	Stimulation of ovaries/testes

Regarding the basophilic cells, the hypothalamus only produces releasing hormones, whereby thyrotropin-releasing hormone (TRH) stimulates thyrotropic cells, corticotropin-releasing hormone (CRH) stimulates corticotropic cells and gonadotropin-releasing hormone (GRH) stimulates gonadotropic cells.

Tables 2 and 3 list all hormones of the hypothalamus and the anterior pituitary, including their respective functions.

Hypothalamus–Pituitary–Thyroid (HPT) Axis

The control of the thyroid gland via the HPT-axis begins with the release of hypothalamic TRH, which travels to the anterior pituitary via the hypophyseal portal vein, where TSH is released consequently. This reaches the thyroid via the regular blood stream and here induces the cleavage of the thyroid hormones from the stored colloid. These hormones are triiodothyronine (T_3) and tetraiodothyronine (T_4), aka thyroxine, whereby the latter is produced in greater quantities while the first is the more bioactive hormone. T_4 therefore constitutes a reservoir of T_3 and is deiodinated in the target tissues. Due to the necessity of iodine, which cannot be produced by humans, for the creation of thyroid hormones, the action of the gland is slightly more complex than that of other endocrine glands. The endocrine cells of the thyroid form follicles (wherefore they are mostly referred to as thyroid follicular cells) and produce the peptide thyroglobulin, which is rich in tyrosyl moieties, and release it into the follicular lumen, where it is bound to iodine taken up from food. Thyroglobuline bound to iodine is referred to as colloid. Through this mechanism the body is able to store the otherwise soluble iodine, thereby becoming less dependent on a constant food-intake. Upon stimulation by TSH the stored colloid is then taken back up into the thyroid follicular cell within storage vesicle. These vesicle then fuse with primary lysosomes, whereupon the colloid is cleaved into T_3 and T_4 and peptide residues.

The dependency of the thyroid on iodine intake via nourishment may, in cases of iodine deficiency, lead to compensatory hypertrophy of the gland; a so-called goiter. Due to the lack of iodine, the otherwise healthy thyroid is not able to inhibit the production of TRH and TSH via the HPT-axis, since it lacks iodine to produce it own hormones, which have a negative feedback effect on the HPT-axis. Thus, the gland is constantly overstimulated by the pituitary, wherefore it grows into a pathological size. As thyroid hormones are vital for brain development, iodine deficiency in pregnant women and newborn children leads to severe mental retardation (so-called cretinism). The World Health Organization estimates that a third of the patients suffering from iodine deficiency are of school age, wherefore it considers this condition as the single most preventable cause of mental retardation worldwide. Iodine is naturally found in marine salt, wherefore seafood is an important source of iodine. Additionally, many other food sources, mainly household salt, flour, water and milk, are often added iodine, especially in areas where iodine deficiency is common.

Another common cause of a developing goiter is the autoimmune Graves' disease. Here, autoantibodies against the TSH receptor stimulate said receptor constitutively, wherefore patients suffer from an enlargement of the thyroid but, unlike in iodine deficiency, from hyperthyroidism rather than hypothyroidism (provided, Graves' disease does not occur in patients with additional iodine deficiency). Since TSH receptors, for currently unknown reasons, are also expressed in the retrobulbar orbital fat and the striated muscle of the eye, Graves' disease additionally causes endocrine orbitopathy, the main symptoms of which are a protruding eyeball (exophthalmus) and the inability to focus both eyes on the same point (strabismus).

Apart from idiopathic forms of hypo- and hyperthyroidism, the other common cause of thyroid insufficiency is the T-cell-mediated autoimmune disease Hashimoto's thyroiditis. It is of importance to note that hyper- and hypothyroidism lead to severe affective changes, with hyperthyroidism leading to mania-like symptoms and hypothyroidism being the most important differential diagnosis for depression.

Hypothalamus–Pituitary–Adrenocortical (HPA) Axis

Upon binding of CRH, the corticotropic cells of the anterior pituitary produce POMC, whereof ACTH is an important post-translational product. ACTH stimulates the middle and inner layers of the adrenal cortex (fasciculate and reticular zones) to produce glucocorticoids and androgens, respectively. The former group of hormones, alongside the catecholamines, are important

factors in the body's stress-response, wherefore it major agent in humans (cortisol) is often referred to as a stress-hormone.

Apart from psychological issues like depression and chronic stress, the most common endocrinological disorders involving the HPA-axis are its hyperfunction (Cushing's disease) as well as its hypofunction (Addison's disease). Both conditions can either be caused by over-/underactive adrenocortical cells or by hyper-/hypofunctions of the respective HPA-axis cells in the pituitary (or rarely the hypothalamus).

Hypothalamus–Pituitary–Gonadal (HPG) Axis

Gonadotropic cells of the anterior pituitary are stimulated upon binding of GnRH to produce LH and FSH. While in males it is commonly believed that FSH and LH are released relatively constitutively (although contrary opinions suggest a hormonal cycle in men, somewhat comparable to that of women), in women the plasma levels of both hormones change throughout the menstrual cycle. Acting in synergy, in men both hormones bind to Leydig cells and lead to testosterone production and stimulate spermatogenesis, while in women FSH stimulates follicular growth in the ovaries by binding to granulosa cells (which produce estrogens) and LH stimulates the follicle-surrounding theca cells to produce androgens and hormonal precursors for the production of estrogens. When the ovarian follicle has fully matured (now called a Graafian follicle) it briefly stops estrogen-production, leading to a decrease in negative feedback via the HPT-axis, which in turn leads to a sudden 24–48 h increase in LH-levels. This increase both induces ovulation as well as the conversion of the follicular residue to the corpus luteum. In case of pregnancy, luteal function is supplanted by that of a similar hormone (human chorionic gonadotropin, hCG) produced by the fetal placenta.

Posterior Pituitary

The hormones ADH and oxytocin are produced by the paraventricular and suprooptic nuclei of the hypothalamus, stored in vesicles and transported anterogradely long the axons to the posterior pituitary. Here, they are calcium-dependently released from the Herring bodies into the bloodstream and travel to various organs of the body. The main effect of ADH is the induction of insertion of aquaporin channels into the membranes of the epithelia of the collecting ducts of the kidney. These channels allow for a higher rate of reabsorption of water from the primary urine, wherefore ADH reduces the amount of total urine that reaches the ureters, thus retaining water in the body. In high doses (i.e., when given as a pharmacological agent) or in cases of hypovolemic shock, ADH also increases vasoconstriction, wherefore it is also known under the names of vasopressin or arginine vasopressin (AVP). Additionally, ADH is released directly into the CNS where increasing evidence suggests its role in social, sexual and maternal behavior. It is also believed to have analgesic effects.

Oxytocin is named after its major effects on the uterus during labor (Greek: okys 'fast' and tokos 'birth'), where it assists cervical dilation and uterine contractions. It also causes the injection of milk into the sinuses of the mammary gland (letdown reflex), from where the milk is able to be excreted via the nipple. In both sexes, oxytocin is believed to be vastly important for orgasm, as it acts strongly anxiolytically and induces a feeling of contentment and security with the mate, thereby allowing for orgasm to occur. It is released in high doses during stimulation of the pelvic floor, genital area and areolas. It is therefore believed that maintaining a sufficient pelvic and genital stimulation for oxytocin release in women was one of the major reasons for the extreme evolutionary growth in girth of the male penis in comparison to other primates of similar body size; in consequence of the human species' extreme thickening of the pelvic floor as an adaptation to bipedal gait.

Studies show elevated oxytocin-levels after orgasm, both in cases of self-stimulation as well as coitus, and during/after parturition. It is therefore commonly accepted that oxytocin plays a vital role in pair- and mother/child-bonding. Studies in rodents show that induced genetic dysfunctions of oxytocin-action lead to severe impairment in female offspring-rearing behavior, which can be attenuated by supplication of oxytocin. In humans, oxytocin is also believed to facilitate trust and romantic attraction to potential sexual mates as well as subsequent monogamous pair bonding.

Finally, due to its importance for social emotions and interactions, the oxytocin-system is believed to be causally, at least in part, involved in autism-spectrum disorders.

Afferent and Efferent Neuronal Connections of the Hypothalamus

With the major exception of the pituitary, (dorsal) thalamus and midbrain ventral tegmental area (VTA), which all only receive projections from the hypothalamus, neuronal connections between the hypothalamus and other areas of the brain are mainly reciprocal. Due to its basal function in maintaining of bodily homeostases, the hypothalamus is connected with most parts of the primate brain. Within the telencephalon it communicates with vast areas of the neocortex as well as the septal area/basal forebrain/substantia innominata and the hippocampal formation and extended amygdala (including the bed nucleus of the stria terminalis).

Within the midbrain and pons, the hypothalamus communicates with, inter alia, the periaqueductal gray, monoaminergic centers, nucleus motorius tegmenti, reticular formation and parabrachial nuclei. The myelencephalic regions of interconnectivity with the hypothalamus are vegetative areas of the reticular formation, parasympathetic nuclei of the cranial nerves (via the posterior longitudinal fasciculus), area postrema and the nuclei of the solitary tract.

The hypothalamus is also bidirectionally connected to the layers I and X of the spinal cord, receives projections from the layer V of the spinal cord and the caudal parts of the spinal nucleus of the trigeminal nerve and projects into the intermediolateral column of the spinal cord, which contains preganglionic sympathetic neurons.

Hypothalamic Functions

Regulation of Vegetative Systems and Adaptation to Stress

The hypothalamus directly influences the activity of the preganglionic parasympathetic nuclei of the cranial nerves via

the posterior longitudinal fasciculus. Of these nuclei, the accessory nucleus of the oculomotor (III) nerve, aka Edinger-Westphal nucleus, sends projections to the ciliary ganglion within the orbit. This ganglion controls the activity of all smooth muscles in the eye (i.e., the ciliary muscle and the sphincter and dilatator muscles of the pupil) as well as the superior tarsal muscle within the upper eyelid. The superior and inferior salivatory nuclei project to the pterygopalatine, submandibular and otic ganglia via the intermediate portion of the facial nerve (VII) and the glossopharyngeal nerve (IX). These ganglia control all exocrine glands of the head; i.e., the salivary glands and the lacrimal gland. The last parasympathetic nucleus in the brain is the dorsal nucleus of the vagus nerve (X), which projects onto uncountable ganglia within the walls of all vegetatively innervated organs of the neck, thorax and large parts of the abdomen. The pelvic organs and outer genitalia as well as the last part of the large intestine (i.e., the descending colon, sigmoid and rectum, including the inner anal sphincter) are controlled by the sacral parasympathetic neurons of the spinal cord, which, in turn, are also regulated by the hypothalamus.

Via the aforementioned projections to the intermediolateral column of the spinal cord, the hypothalamus also controls the sympathetic nervous system.

It has to be mentioned, however, that hypothalamic control of most vegetative function is not to be mistaken for an induction of said function. Most bodily systems function autonomously and also have an inherent set of mechanisms for the maintenance of a minimal degree of homeostasis. Notable examples hereof are the expiratory and inspiratory centers within the myelencepahlic reticular formation, the spontaneously firing neurons in the wall of the esophagus, stomach and intestines and last but not least the cardiovascular system, which is, possibly, the most intricately maintained of all peripheral organ systems. Its base activity is controlled through the sinoatrial node, a group of cardiac muscles with the capacity of spontaneous and rhythmic depolarization. The adaptation of the heart and vessels to in–or decreasing cardiac activity is also based on internal reflexes, such as the Frank-Starling reflex of the heart and the Windkessel effect of the large arteries. Finally, the amount of fluid within the cardiovascular system, and thereby largely also the blood pressure, is kept at an optimum through the kidneys, which – through their complex duct system – produce an extensively excess amount of primary urine, whereof, however, averagely up to 98% is reabsorbed specifically depending on the osmotic pressure within the tissue. The role of the hypothalamus is therefore primarily one of integration and adaption to extraordinary circumstances.

An extensively investigated example hereof is the so-called carotid sinus-reflex: The bifurcation of the common carotid artery is richly supplied with baroceptors within a dilated area of the arterial wall (the carotid sinus). The carotid sinus is innervated by a branch of the glossopharyngeal nerve (IX), the sinus nerve of Hering, which relays changes in blood pressure to the nuclei of the solitary tract. This information is then passed on to the hypothalamus, which, in turn, reacts to maintain optimal blood pressure by adapting the dilation of the carotid artery via the dorsal nucleus of the vagus nerve (X). Similar baroceptors also exist in the aortic arch; their information being relayed to the nuclei of the solitary tract via the vagus nerve (X).

Apart from adaptation to extreme changes in internal homeostatic values, the hypothalamus plays a major role in the adaptation to (external) stressors. This is achieved via activation of the sympathetic and inhibition of the parasympathetic nervous system as well as through activation of the HPA-axis. The increases in plasma cortisol and catecholamines thereby work in synergy with each other and the increase in sympathetic activity. While humoral and synaptic catecholamines increase many bodily functions at the expenditure of energy, which in stress-situations is mainly derived from glucose, cortisol increases the amount of glucose available to the body, mainly the striated muscles. Therefore, an important other synergist in the adaptation to stress is the pancreatic hormone insulin, which enables the integration of glucose-transporters into cellular membranes.

Regulation of Water Balance

Although, as mentioned above, the basic control over water balance is performed peripherally by the kidneys, the hypothalamus may regulate kidney function on the one hand and, on the other, is essential for the motivation toward drinking behavior and the development of thirst.

The production and – via the posterior pituitary – release of ADH results from the detection of low blood pressure and high blood osmolarity by the hypothalamus. Herefore, the hypothalamus uses three major mechanisms of detection:

- On the one hand, the ependyma lining the base of the third ventricle, where the hypothalamus is situated, consists partly of specialized ependymal cells, the so-called tanycytes. These cells have long processes that protrude into the hypothalamic tissue and convey signals from the cerebrospinal fluid (CSF) to the CNS. It is believed that this mechanism enables the hypothalamus to monitor not only the osmolarity but also the protein- and metabolic content of the CSF.
- Secondly, the hypothalamus receives projection from the circumventricular organs (CVOs). These regions of the brain are highly vascularized and are characterized by their lack of a tight blood–brain barrier, wherefore they can monitor the contents of the blood stream in a fashion unique within the CNS. The most notable sensory CVOs are the area postrema (AP), the subfornical organ (SFO) and the organum vasculosum of the lamina terminalis (OVLT). The SFO and OVLT, both situated near the third ventricle, relay osmosensory information to the hypothalamus and, due to their modified and less tight blood–brain barrier, are a threshold for peptides and hormones into the CFS.
- The third mechanism of hypothalamic monitoring of the blood is via peripheral sensory (or nonchromaffin) paraganglia. These organs consist of small clusters of chemoceptors and are considered the most richly vascularized organs in the body, wherefore Kummer described their function as, literally, 'tasting the blood.' Two important sensory paraganglia are the carotid and aortic glomera (or bodies), which relay their chemoinformation to the

nuclei of the solitary tract and thereafter the hypothalamus in the same fashion as explained above for the baroceptors of the carotid sinus and the aortic arch.

Apart from the release of ADH for the regulation of water balance, the hypothalamus is involved in a second hormonal system essential for fluid and electrolyte level maintenance, the renin-angiotensin-aldosterone-system (RAAS), whereby is has to be noted that the ADH-system and the RAAS interact with each other. The kidney possesses two monitoring stations for the fluid and electrolyte levels, both within a part of the nephron called the juxtaglomerular apparatus. On the one hand, modified smooth muscle cells of the efferent arterioles in the kidney (the juxtaglomerular cells) detect decreases in blood pressure, and on the other, the macula densa within the distal tubule of the nephron is sensitive to decreases of sodium chloride in the primary urine. Both signals lead to the release of the hormone renin by the juxtaglomerular cells, which converts the freely available prohormone angiotensinogen within the blood plasma to angiotensin I. This is, in turn, converted to angiotensin II by angiotensin-converting enzyme (ACE). Angio II has potent vasoconstrictive effects, leads to the release of the hormone aldosterone from the adrenal cortex (thereby leading to higher sodium and water reabsorption in the kidney) and, finally, induces the release of ADH from the posterior pituitary. Additionally, angio II is detected by the SFO and OVLT and leads the hypothalamus to induce the sensations of thirst and a desire for salt via the median preoptic nucleus.

The area postrema is also involved in water balance. Although primarily responsible for the induction of vomiting behavior when toxins are detected either in the blood or in the intestine, it has also been shown to be sensitive to angiotensin II and, thus, also increases water-seeking behavior through projections to the median preoptic nucleus of the hypothalamus.

The mechanism through which the hypothalamus actually induces the active search for water supplies is believed to be projections to the substantia innominata (SI), possibly the nucleus basalis of Meynert. Through projections from the bed nucleus of the stria terminalis (BST), indirectly from the prefrontal cortex, amygdala and hippocampal formation via the ventral lateral septal nucleus as well as from the supra-chiasmatic nucleus (SCN) it is believed that thirst and induction of water-seeking behavior and drinking can be adapted not only to sleep–wake cycles but also to acute emotional circumstances.

Regulation of Feeding

Due to original studies in rodents from the 1940 and 1950s, it was long believed that the hypothalamus included two discrete areas; one with hyperphagic and the other with hypophagic effects. Recent findings have, however, shown that the major regulation of hunger and food intake is actually performed by the same hypothalamic area, namely the arcuate nucleus. These results are based on the discovery of the gene encoding for the adipocyte-derived hormone leptin. Knockout of the rodent ortholog of the LEP/OB gene (LEP for leptin or OB for obesity) leads to an incapability of the animals to experience satiety, thus leading to obesity. Hence, leptin produced by adipocytes binds to leptin-receptors in the hypothalamic arcuate nucleus

Figure 4 Leptin-action within the hypothalamus (a-MSH: alpha-melanocyte stimulating hormone; AgRP: agouti-related protein; MCH: melanin-concentrating hormone; NPY: neuropeptide Y; ORX: orexin; TRH: thyrotropin (TSH) releasing hormone. Red arrows indicate inhibition and green arrows indicate stimulation).

and here induces satiety. The mechanism of leptin-action is complex, as it acts simultaneously on two populations of neurons within the arcuate nucleus. Of these, neuropeptide Y (NPY) and Agouti-related protein (AgRP) expressing cells are inhibited through leptin, whereas POMC/α-MSH expressing cells are activated. NPY and AgRP are considered orexigenic (i.e., appetite-stimulating) and α-MSH anorexigenic (i.e., appetite-inhibiting). The effects of both peptide-groups is mediated through the lateral hypothalamic area, which produces the peptides orexin (ORX) and melanin-concentrating hormone (MCH), as well as the paraventricular nucleus through the induction of TRH-production. TRH, MCH and ORX activate the metabolism and induce hunger and food-seeking behavior. The production of TRH, MCH and ORX is inhibited by α-MSH and activated by NPY and AgRP. Thus, leptin binding to the neurons of the arcuate nucleus activates α-MSH-producing cells, which, in turn, inhibit TRH, MCH and ORX-production, as well as inhibits NPY/AgRP-producing cells, which otherwise would activate TRH, MCH and ORX-production. Through both pathways, therefore, increases in leptin-concentration lead to reduction of hunger and food-seeking behavior (q.v., Figure 4).

Regulation of Ultradian, Circadian and Infradian Rhythms

The aforementioned hypothalamic neuropeptide orexin is, although shown to be involved in appetite and food-seeking behavior, primarily responsible for the regulation of wakefulness and arousal. The clinical picture of narcolepsy, where patients experience excessive daytime sleepiness and often sudden onset naps that are often not controllable, has repeatedly been linked to dysfunctions in the orexin-system. In humans, it is believed to be caused by autoimmune processes that destroy orexin-producing cells with mutations in the human leukocyte antigen (HLA; aka major histocompatibility complex, MHC) appearing to be the most common biological foundation. In animals, genetic knockout of the genes encoding for orexin or its receptors causes the clinical picture found in human narcolepsy patients.

Research in mice has also shown that hypothalamic neurons of the tuberomammillary nuclei producing histamine show distinct firing patterns during different sleep cycles and transition-phases between sleep and waking. The projections of the hypothalamus to the substantia innominata and nucleus basalis of Meynert are also considered relevant in the regulation of arousal and attention. They comprise a branch of the ascending reticular arousal system, a network of cholinergic projections ascending from the brainstem through the hypothalamus and allothalamus to the striatum and, via the nucleus basalis of Meynert, to the cerebral cortex. Finally, through the HPA-axis, the hypothalamus regulates the levels of the glucocorticoid-production by the adrenal cortex. In humans, the most important of these is the steroid hormone cortisol and is also involved in the induction and upkeep of alertness and, by extension, wakefulness. A common hypothesis, regarding the postwaking sudden increase in plasma cortisol (the cortisol-awakening-reaction, CAR), is that it increases the alertness of a recently awakened individual and, thus, aids in preparation for the possible dangers and increased requirements of waking hours.

The regulation of temporary cycles, which can be approximately the same length as 1 day (circadian), shorter than a day (ultradian) and considerably longer (infradian, even circa-annual) are largely dependent on light. The hypothalamus is therefore strongly connected with specialized ganglion cells in the retina, that project information regarding ambient illumination directly to the hypothalamus via the retinohypothalamic tract. These ganglion cells are receptive for light of blue wavelength, thus constituting primary photoceptors, but do not relay visual information, merely the information how much light acutely falls on the retina. The projections are relayed in the hypothalamic suprachiasmatic nucleus (SCN) and, from there, project to the intermediolateral column of the cervical spinal cord. Via the superior cervical ganglion, which is the most cranial of the paravertebral sympathetic ganglia, the cervical sympathetic fibers activate the pineal gland of the epithalamus. The SCN thus indirectly has control of the conversion of serotonin to melatonin within the pineal gland by influencing the activity of the enzyme serotonin N-acetyltransferase; in a fashion that melatonin production is induced in the dark. Therefore, melatonin levels not only change over the course of a day but also depending on seasonal changes and even an individual's position related to the earth's circles of latitude (aka parallels). Thus, affective disorders related to the melatonin production (seasonal affective disorders, SAD; aka winter depressions) are more common in Scandinavian countries and can be treated by bright light therapy. This is strengthened by findings regarding both native and Canadian Icelandic people who, although being or descending from within Scandinavia, show surprisingly low levels of SAD; a fact which is believed to be explainable through their high nutritional intake of Vitamin D through fish. Vitamin D synthesis is alternatively also induced by exposure to sunlight.

Many processes regulated through the hypothalamus, not only sleep–wake cycles, follow rhythmic patterns. The example of the circadian rhythm of the HPA-axis has also been given. Another important rhythmic system is the infradian regulation of the estrous cycle in females through the HPG-axis. It can therefore be concluded, that the hypothalamus not only maintains internal bodily homeostases, but also aligns these homeostases to external stimuli dependent on regular changes in terrain conditions.

Regulation of Sexual and Reproductive Behavior

As mentioned previously, the brain in general and the hypothalamus in particular are highly sexually dimorphic regions of the mammalian body. Apart from the differences in HPG-axis-regulation and thereby the control over the female estrous cycle, the hypothalamus has also been described above as being involved in parturition and lactation through the hormones oxytocin and prolactin. The latter is a highly versatile signaling agent, but has important function during the induction of lactation but also in postorgasmic phases, where it is believed responsible for the feeling of sexual gratification.

The most commonly examined hypothalamic nucleus regarding sexual behavior and diversity is the sexually dimorphic nucleus (SDN); the human homologue thereof is the third interstitial nucleus of the anterior hypothalamus (INAH3). Together with other regions of the di- and telencephalon (e.g., the amgydala, bed nucleus of the stria terminalis, lateral septal nucleus and the nucleus of the diagonal band of Broca), including the hypothalamic ventromedial, infundibular, ventral premammillary, suprachiasmatic and medial preoptic nuclei, this system is referred to by Nieuwenhuys et al. (2008) as the telodiencephalic reproductive complex (TDRC). The connection with the amygdala, a primary telencephalic center for the interpretation and reaction-decision regarding conspecifics and other socially relevant stimuli, links sexually reproductive behavior with other socially relevant behaviors, such as defense and aggression.

Although this aspect is to extensive to cover in detail, it has been shown in rodents that the areas of the TDRC are differently sized between sexes and that injection of different sexually relevant agents (e.g., aromatase(-inhibitors) or testosterone) into nuclei of the TDRC at an early age leads to significant changes in sexual behavior, such as females mounting other sexually receptive females or males showing female-typical lordosis behavior in the presence of other males. The size of TDRC-areas, especially the INAH3, is also intensively discussed as a possible correlate of human sexual orientation. This notion goes back mainly to a paper published by LeVay (1991), although it implications are often overrated; as also repeatedly maintained by LeVay himself.

Studies using positron emission tomography (Savic et al., 2005; Berglund et al., 2006) also showed that arousal of TDRC-regions to testosterone-derivatives and estrogen-like compounds is consistent with sexual orientation, whereby homosexual men and heterosexual women as well as homosexual women and heterosexual men share arousal to either male or female scent, respectively. It should, however, be mentioned that the accessory olfactory system, which in mammals is responsible for the perception and transduction of pheromonal information, is highly vestigial in humans and the question of its being functional is highly debated.

Regulation of Body Temperature and the Immune System

Through the HPA-axis as well as the projections from the spinal interomediolateral column to the adrenal medulla, the

hypothalamus has considerable influence over the immune response. Important in this context is the notion that immunocytes are not equally influenced by cortisol and catecholamines. Thus, antiinflammatory immune responses are not directly under the influence of the hypothalamus, while proinflammatory immunocytes have several receptors for the aforementioned hormones. Since the pro- and antiinflammatory immunocytes do, however, influence each other, activation of the HPA-axis and the adrenal medulla lead to a shift of the immune response toward the antiinflammatory branch. This has been shown, additionally, to be different for acute verses chronic stress, whereby the first leads to an overall increase in immune response, while the latter will lead to immunosuppression. This has been shown for several factors such as immunocyte concentration and activity, autoimmune regulation, wound healing and susceptibility to clinically induced infection. Importantly, in neoplastic disorders the influence of HPA-axis and adrenal medullary hormones have repeatedly been shown to have severely dire consequences on remission rates and patients' survival. It is therefore essential to note, that a reduction of hypothalamically induced stress-response (e.g., through accompanying psychooncological therapy) has considerable beneficial consequences in cancer patients, whereby the actual form of coping-behavior and therapy is not of relevance, as patients have been shown to 'instinctively choose' the form of coping/therapy that is best suited for them individually.

Closely linked, but not only related to immune response, is the regulation of body temperature by the hypothalamus. In case of bacterial (and a few strains of viral) infection, the hypothalamus raises the index value for body temperature, thereby inducing fever. Apart from its participation in the active immune response, this also influences the motivational and appetitive reactions and behavior in mammals. Taken together, the physiological and behavioral changes during active immune response are called sickness behavior and are interpreted as an attempt to conserve energy and reduce risk of additional dangers (e.g., through other predators). It has been shown, for example, that sickness behavior reduces the motivation toward food-seeking behavior as well as the appetitive component of hunger but not the actual hunger or desire for food intake, as patients given food (by persons of trust) will eat this, even though they will show a reduction in activities necessary for the production of foods.

Abstract

A statistical hypothesis is a statement about one or more population parameter(s). A hypothesis test is a rule for deciding which of two complementary hypotheses is true, based on some data. Various methods for constructing hypothesis tests (e.g., likelihood, Bayesian, intersection–union) are available. Various measures for evaluating hypothesis tests, most of which are related to the tests' probabilities of making correct or incorrect decisions, are available, also. Construction and evaluation of tests, if a large sample is available, is sometimes simplified by asymptotic results.

Introduction

A *statistical hypothesis* is a statement about one or more population parameter(s), and the two complementary hypotheses in a hypothesis-testing problem are called the *null hypothesis* and the *alternative hypothesis*. They are denoted by H_0 and H_1, respectively.

If θ denotes a population parameter, the general format of the null and alternative hypotheses is $H_0: \theta \in \Theta_0$ and $H_1: \theta \in \Theta_0^c$, where Θ_0 is some subset of the parameter space and Θ_0^c is its complement. A hypothesis test is a rule for deciding whether H_0 or H_1 is true, based on some data. Typically, a hypothesis test is specified in terms of a *test statistic*, $W(X_1, \ldots, X_n) = W(\boldsymbol{X})$, a function of the data, $\boldsymbol{X}$. The sample space for W is partitioned into the *rejection region*, R, and its complement, the *acceptance region*. If $W \in R$ is observed, the null hypothesis H_0 is rejected, and the decision is made that H_1 is true. If $W \notin R$, H_0 is accepted as true.

For example, in a study to examine the factors that influence a student's success at completing a 4-year college, one factor of interest might be socioeconomic status (SES). If, for simplicity, we just have two groups (high SES and low SES), and the success probabilities of the respective groups are p_h and p_l, then a hypothesis test of interest may be $H_0: p_h \le p_l$ versus $H_1: p_h > p_l$.

This is an example of a one-sided test, in which the alternative hypothesis specifies a direction. In contrast, we may consider the two-sided test, $H_0: p_h = p_l$ versus $H_1: p_h \ne p_l$, in which no direction is specified in the alternative. If we let $\widehat{p}_h$ and $\widehat{p}_l$ denote the observed success rates in the two SES classes, the one-sided test would reject the null hypothesis if $\widehat{p}_h - \widehat{p}_l$ is big, while the two-sided test would reject the null hypothesis if $\widehat{p}_h - \widehat{p}_l$ is either big or small.

A hypothesis test of H_0: $\theta \in \Theta_0$ versus H_1: $\theta \in \Theta_0^c$ might make one of two types of errors. If $\theta \in \Theta_0$, but the hypothesis test incorrectly decides to reject H_0, then the test has made a *Type I error*. If, on the other hand, $\theta \in \Theta_0^c$, but the test decides to accept H_0, a *Type II error* has been made. In our example of testing H_0: $p_h \le p_l$ versus H_1: $p_h > p_l$, if we conclude that $p_h > p_l$, but in fact $p_h \le p_l$, we have made a Type I error.

Constructing Tests

There are many methods of deriving test statistics for a hypothesis test, a few of which follow.

Likelihood Ratio Tests

The likelihood ratio method of hypothesis testing is related to maximum likelihood estimators (MLE) (discussed in *Estimation: Point and Interval*). Suppose that we have a sample, $X_1, \ldots, X_n$, where the X_i are independent, each with distribution given by the probability density or mass function, $f(x|\theta)$. The observed values of these random variables are denoted by $\boldsymbol{x} = (x_1, \ldots, x_n)$, with likelihood function $L(\theta|\boldsymbol{x})$ given by

$$L(\theta|\boldsymbol{x}) = \prod_{i=1}^{n} f(x_i|\theta).$$

The *likelihood ratio test (LRT) statistic* for testing H_0: $\theta \in \Theta_0$ versus H_1: $\theta \in \Theta_0^c$ is

$$\lambda(\boldsymbol{x}) = \frac{\sup\limits_{\Theta_0} L(\theta|\boldsymbol{x})}{\sup\limits_{\Theta} L(\theta|\boldsymbol{x})}$$

An LRT is a test that has a rejection region of the form $\{\boldsymbol{x}: \lambda(\boldsymbol{x}) \le k\}$, where k is any number satisfying $0 \le k \le 1$.

If we interpret the likelihood function as measuring how likely the values of θ are, then we see that the LRT statistic is comparing the plausibility of the θ values in the null hypothesis with those in the alternative. Small values of the LRT statistic are then interpreted as being evidence against H_0 and lead to rejection of H_0.

If the null hypothesis consists of a single value θ_0, and the alternative is everything else, then the LRT statistic is simply $\lambda(\boldsymbol{x}) = \frac{L(\theta_0|x)}{L(\widehat{\theta}|x)}$, where $\widehat{\theta}$ is the MLE of θ.

Example. Let $X_1, \ldots, X_n$ be a random sample from a normal population with mean θ and variance 1 ($n(\theta, 1)$ population). The LRT statistic for testing H_0: $\theta = \theta_0$ versus H_1: $\theta \ne \theta_0$ is

$$\lambda(\boldsymbol{x}) = \frac{L(\theta_0|\boldsymbol{x})}{L(\overline{x}|\boldsymbol{x})} = \frac{(2\pi)^{-\frac{n}{2}} \exp\left[-\sum_{i=1}^{n} \frac{(x_i-\theta_0)^2}{2}\right]}{(2\pi)^{-\frac{n}{2}} \exp\left[-\sum_{i=1}^{n} \frac{(x_i-\overline{x})^2}{2}\right]},$$

where $\overline{x}$ is the sample mean calculated from $\boldsymbol{x}$.

If $T(\boldsymbol{X})$ is a sufficient statistic for θ, then, as with MLE, the LRT statistic is a function of T. That is, $\lambda(\boldsymbol{x})$ depends on $\boldsymbol{x}$ only

through $T(\boldsymbol{x})$. In the previous example $T(\boldsymbol{X}) = \overline{X}$ is a sufficient statistic, and the expression for $\lambda(\boldsymbol{x})$ can be simplified to

$$\lambda(\boldsymbol{x}) = \exp\left[-\frac{n(\overline{x}-\theta_0)^2}{2}\right].$$

Bayesian Tests

The Bayesian paradigm prescribes that the sample information be combined with the prior information using Bayes' theorem to obtain the posterior distribution, $\pi(\theta|\boldsymbol{x})$. All inferences about θ are now based on the posterior distribution. In a hypothesis-testing problem, the posterior distribution may be used to calculate the probabilities that H_0 and H_1 are true.

One way a Bayesian hypothesis tester may choose to use the posterior distribution is to decide to accept H_0 as true if

$$\frac{P(\theta \in \Theta_0|\boldsymbol{X})}{P(\theta \in \Theta_0^c|\boldsymbol{X})} > k,$$

for some constant k, and to reject H_0 otherwise. Equivalently, she can reject H_0 if $P(\theta \in \Theta_0^c|\boldsymbol{X}) \geq 1/(1+k)$.

Example. Let $X_1, \ldots, X_n$ be a random sample from an $n(\theta, \sigma^2)$ population, and let the prior distribution on θ be $n(\mu, \tau^2)$, where σ^2, μ, and τ^2 are known. Consider testing $H_0{:}\theta \leq \theta_0$ versus H_1: $\theta > \theta_0$, and suppose we decide to accept H_0 if $P(\theta \in \Theta_0|\boldsymbol{X}) > P(\theta \in \Theta_0^c|\boldsymbol{X})$. After some calculation, we find that H_0 will be accepted as true if

$$\overline{X} < \theta_0 + \frac{\sigma^2(\theta_0-\mu)}{n\tau^2}.$$

Union–Intersection and Intersection–Union Tests

In some situations, tests for complicated null hypotheses can be developed from tests for simpler null hypotheses. The union–intersection method of test construction might be useful when the null hypothesis is conveniently expressed as an intersection, say $H_0{:}\theta \in \bigcap_{\gamma\in\Gamma}\Theta_\gamma$, where Γ is an arbitrary index set. If tests are available for each of the problems of testing $H_{0\gamma}{:}\theta \in \Theta_\gamma$ versus $H_{1\gamma}{:}\theta \in \Theta_\gamma^c$, where the rejection region for the test of $H_{0\gamma}$ is $\{\boldsymbol{x}{:}\ W_\gamma(\boldsymbol{x}) \in R_\gamma\}$, then the rejection region for the union–intersection test is

$$\bigcup_{\gamma\in\Gamma}\{x{:}W_\gamma(x) \in R_\gamma\}.$$

The rationale is that if any one of the hypotheses $H_{0\gamma}$ is rejected, then H_0 must be rejected, also.

A complementary method, the intersection–union method, may be useful if the null hypothesis is conveniently expressed as a union. Suppose we wish to test the null hypothesis $H_0{:}\theta \in \bigcup_{\gamma\in\Gamma}\Theta_\gamma$, and $\{\boldsymbol{x}{:}W_\gamma(\boldsymbol{x}) \in R_\gamma\}$ is the rejection region for a test of $H_{0\gamma}{:}\theta \in \Theta_\gamma$ versus $H_{1\gamma}{:}\theta \in \Theta_\gamma^c$. Then the rejection region for the intersection–union test of H_0 versus H_1 is

$$\bigcap_{\gamma\in\Gamma}\{\boldsymbol{x}{:}W_\gamma(\boldsymbol{x}) \in R_\gamma\},$$

and H_0 is false if and only if all of the $H_{0\gamma}$ are false, so H_0 can be rejected if and only if each of the individual hypotheses $H_{0\gamma}$ can be rejected.

Example. Returning to our example about success in 4-year colleges, we might argue that there are measures of success other than finishing. For example, yearly income could be used to measure success, and denoting mean incomes in the high and low SES groups θ_h and θ_l, respectively, results in the hypothesis test

$$H_0{:}\theta_h \leq \theta_l \text{ or } p_h \leq p_l \quad \text{versus} \quad H_1{:}\theta_h > \theta_l \text{ and } p_h > p_l,$$

where the high group is considered superior only if H_1 is accepted.

If we have estimators $\widehat{\theta}_h$, $\widehat{\theta}_l$, $\widehat{p}_h$, and $\widehat{p}_l$, a rejection region for the intersection–union test could be given by

$$\left\{\left(\widehat{\theta}_h, \widehat{\theta}_l, \widehat{p}_h, \widehat{p}_l\right){:}\widehat{\theta}_h - \widehat{\theta}_l > k_1 \text{ and } \widehat{p}_h - \widehat{p}_l > k_2\right\}.$$

Thus the intersection–union test decides that the high SES group is superior to the low SES group, that is, H_1 is true, if and only if it decides that each of the individual parameters is better in the high group.

Intersection–union tests provide important tools in acceptance sampling, in which one decides whether to accept a product based on a collection of measurements (see Berger, 1982).

There are many other methods available for constructing hypothesis tests, methods based on invariance, pivots, robust, or large-sample arguments, to name a few. For more on hypothesis testing see Lehmann (1986).

Evaluating Tests

As mentioned previously, a hypothesis test might make one of two different kinds of errors. The probabilities of making these errors can be calculated using the *power function*. If R denotes the rejection region for a test, the *power function* is $\beta(\theta) = P_\theta(\boldsymbol{X} \in R)$. If $\theta \in \Theta_0$, $\beta(\theta)$ is the probability of a Type I error. If $\theta \in \Theta_0^c$, $\beta(\theta)$ is one minus the probability of a Type II error. Hence, a good test has power function near one for most $\theta \in \Theta_0^c$ and near zero for most $\theta \in \Theta_0$.

Example. Let $X_1, \ldots, X_n$ be a random sample from an $n(\theta, \sigma^2)$ population, σ^2 known. The LRT of $H_0{:}\theta \leq \theta_0$ versus $H_1{:}\theta > \theta_0$ rejects H_0 if $\sqrt{n}(\overline{X}-\theta_0)/\sigma \geq k$ and has power function

$$\beta(\theta) = P\left(Z \geq k + \frac{\theta_0-\theta}{\sigma/\sqrt{n}}\right),$$

where Z is a standard normal random variable.

After a hypothesis test is done, the conclusions must be reported in some statistically meaningful way. One method of reporting the results of a hypothesis test is to report the *size* $\left(\alpha = \sup_{\theta\in\Theta_0} P_\theta(\boldsymbol{X} \in R)\right)$ of the test and the decision to reject H_0 or accept H_0. The size of the test carries important information. If α is small, the decision to reject H_0 is fairly convincing, but if α is large, the decision to reject H_0 is not very convincing, because the test has a large probability of incorrectly making that decision. A common practice is to choose the desired small value of α (often 0.05 or 0.01) and then to choose the critical value, k in the previous example, so the resulting test has the specified size, α.

Another way of reporting the results of a hypothesis test, one that is data dependent, is to report the *p-value*. Typically, not one but an entire class of tests is constructed, a different test being defined for each value of α. The p-value for the sample point $\boldsymbol{x}$ is the smallest value of α for which this sample point will lead to rejection of H_0 (*see* Significance, Tests of). Because rejection of

H_0 using a test with small size is more convincing evidence that H_1 is true than rejection of H_0 with a test with large size, the interpretation of p-values goes in the same way. The smaller the p-value, the stronger the sample evidence that H_1 is true.

In the previous example, if data $\boldsymbol{x}$ with sample mean $\bar{x}$ is observed, the p-value is

$$p(\boldsymbol{x}) = P\left(Z \geq \frac{\bar{x} - \theta_0}{\sigma/\sqrt{n}}\right).$$

Many other types of evaluations of tests can be done. The theory of most powerful tests shows how to construct best tests under a variety of conditions (see Lehmann, 1986 or Casella and Berger, 2001: Chapter 8). Hypothesis tests can also be evaluated using risk functions as in Hwang et al. (1992).

Asymptotics

For the LRT statistic, the following general theorem allows the construction of a large-sample test.

Theorem 1. *Let $X_1, \ldots, X_n$ be a random sample from a probability density function or probability mass function $f(\boldsymbol{x}|\theta)$. Under some regularity conditions on $f(\boldsymbol{x}|\theta)$, if $\theta \in \Theta_0$ then the distribution of the statistic $-2\log\lambda(\boldsymbol{x})$ converges to a chi-squared distribution as the sample size $n \to \infty$. The degrees of freedom of the limiting chi-squared distribution is the difference between the number of free parameters specified by $\theta \in \Theta_0$ and the number of free parameters specified by $\theta \in \Theta$.*

The 'regularity conditions' are concerned mainly with the existence and behavior of the derivatives (with respect to the parameter) of the likelihood function, and the support of the distribution (it cannot depend on the parameter). See Casella and Berger (2001: Section 10.6) or Lehmann (1986: Section 8.8) for precise conditions.

Rejection of H_0 for small values of $\lambda(\boldsymbol{x})$ is equivalent to rejection for large values of $-2\log\lambda(\boldsymbol{x})$. Thus, by Theorem 1 the test that rejects H_0 if and only if $-2\log\lambda(\boldsymbol{x}) \geq \chi^2_{\nu,\alpha}$, where ν is the degrees of freedom specified in the theorem, is a test with size approximately equal to α, if the sample size is large.

As might be expected, Theorem 1 has wide applicability. In particular, it is extremely useful in categorical data analysis (*see* Multivariate Analysis: Discrete Variables (Loglinear Models)).

Other large-sample test constructions are based on asymptotic normality of a point estimator (*see* Estimation: Point and Interval). Suppose we wish to test a hypothesis about a real-valued parameter θ, and $W_n = W(X_1, \ldots, X_n)$ is a point estimator of θ based on a sample of size n that satisfies

$$\frac{W_n - \theta}{\sqrt{\mathrm{Var}W_n}} \to Z$$

as $n \to \infty$, where $\mathrm{Var}W_n$ is the variance of W_n and Z is a standard normal random variable. We now have the basis for an approximate test, for example, we would reject $H_0{:}\theta \leq \theta_0$ at level 0.05 if $(W_n - \theta_0)/\sqrt{\mathrm{Var}\,W_n} \geq 1.645$. Note, $\mathrm{Var}\,W_n$ could depend on θ_0, and we can still use it in the test statistic. This type of test, where we use the actual variance of W_n, is called a *score test*.

If $\mathrm{Var}\,W_n$ also depends on unknown parameters, we could look for an estimate S_n^2 of $\mathrm{Var}\,W_n$ with the property that $(\mathrm{Var}\,W_n)/S_n^2$ converges in probability to one. Then, using Slutsky's theorem (see Casella and Berger, 2001: Section 5.5), we can deduce that $(W_n - \theta)/S_n$ converges in distribution to a standard normal distribution, also. The large-sample test based on this statistic is called a *Wald test*.

More details about asymptotic tests may be found in Boos and Stefanski (2013) and Lehmann (1999).

Conclusions

Hypothesis testing is one of the most widely used, and some may say abused, methodologies in statistics. Formally, the hypotheses are specified, an α-level is chosen, a test statistic is calculated, and it is reported whether H_0 or H_1 is accepted. In practice, it may happen that hypotheses are suggested by the data, the choice of α-level may be ignored, more than one test statistic is calculated, and many modifications to the formal procedure may be made. Most of these modifications cause bias and can invalidate the method. For example, a hypothesis suggested by the data is likely to be one that has 'stood out' for some reason, and, hence, H_1 is likely to be accepted, unless the bias is corrected for (using something like Scheffe's method – see Hsu, 1996).

Perhaps the most serious criticism of hypothesis testing is the fact that, formally, it can only be reported that either H_0 or H_1 is accepted at the prechosen α-level. Thus, the same conclusion is reached if the test statistic only barely rejects H_0 and if it rejects H_0 resoundingly. Many feel that this is important information that should be reported, and thus it is commonplace to report the p-value of the hypothesis test, also.

For further details on hypothesis testing see the classic book by Lehmann (1986). Introductions are provided by Casella and Berger (2001) or Schervish (1995), also, and a good introduction to multiple comparisons is Hsu (1996); *see* Hypothesis Tests, Multiplicity of.

Abstract

A test is a statistical procedure to obtain a statement on the truth or falsity of a proposition, on the basis of empirical evidence. After a brief historical account, attention is given to the contrasting approaches of R.A. Fisher's significance tests and J. Neyman and E. Pearson's tests of a null against an alternative hypothesis. The *t*-test is treated as a paradigmatic example and used to illustrate the role of assumptions. The *p*-value and the confidence interval are statistical procedures which are more informative than a test leading merely to the 'reject'/'do not reject' dichotomy. A discussion is presented about problems in the interpretation and use of hypothesis tests, and it is argued that these result to a great extent from our human limitations in reasoning with uncertain evidence. Research results do usually not stand on their own (as assumed in the model of a hypothesis test), but are to be combined with other results, e.g., by meta-analysis.

Hypothesis tests are part of the basic methodological toolkit of social and behavioral scientists. The philosophical and practical debates underlying their application are, however, often neglected. The fruitful application of hypothesis testing can benefit from a clear insight into, the underlying concepts and their limitations.

The Idea of Hypothesis Testing

A test is a statistical procedure to obtain a statement on the truth of falsity of a proposition, on the basis of empirical evidence. This is done within the context of a model, in which the fallibility or variability of this empirical evidence is represented by probability. In this model, the evidence is summarized in observed data, which is assumed to be the outcome of a stochastic, i.e., probabilistic, process; the tested proposition is represented as a property of the probability distribution of the observed data.

Some History

The first published statistical test was by John Arbuthnot in 1710, who wondered about the fact that in human births, the fraction of boys born year after year appears to be slightly larger than the fraction of girls (cf. Hacking, 1965). He calculated that this empirical fact would be exceedingly unlikely (he obtained a probability of 1/483 600 000 000 000 000 000 000) if the probability of a male birth were exactly 0.5, and argued that this was a proof of divine providence, since boys – some of whom will be soldiers – have a higher risk of an early death, so that a higher ratio of male births is needed to obtain an equal ratio of males among young adults. We see here the basic elements of a test: the proposition that the male birth ratio is 0.5, related to data by regarding these as outcomes of stochastic variables, the calculation that the data would be unlikely if the proposition were true, and a further conclusion interpreting the falsity of the proposition.

One of the first statistical procedures that comes close to a test in the modern sense was proposed by Karl Pearson in 1900. This was the famous chi-squared test for comparing an observed frequency distribution to a theoretically assumed distribution. Pearson derived the now well-known statistic to test the proposition, or *hypothesis*, that the probabilities of the various possible (finitely many) outcomes of some random variable are given by certain preassigned numbers. Pearson proved that this statistic has (in a large-sample approximation) the chi-squared distribution; this distribution can therefore be used to calculate the probability that, if the hypothesis holds, the test statistic will assume a value equal to or larger than the value actually observed.

The idea of testing was further codified and elaborated in the first decades of the twentieth century, mainly by R.A. Fisher (1925). In his significance tests, the data are regarded as the outcome of a random variable X (usually a vector or matrix), which has a probability distribution which is a member of some family of distributions; the tested hypothesis, also called the null hypothesis, is an assertion which defines a subset of this family; a test statistic $T = t(X)$, which is a function of X, is used to indicate the degree to which the data deviate from the null hypothesis; and the significance of the given outcome of the test statistic is calculated as the probability, if the null hypothesis is true, to obtain a value of T which is at least as high as the given outcome. If the probability distribution of T is not uniquely determined by the null hypothesis, then the significance is the maximal value of this probability, for all distributions of T compatible with the null hypothesis. The significance probability is now often called the *p*-value (the letter *p* referring to probability). With Fisher originates the convention to consider a statistical testing result as 'significant' if the significance probability is 0.05 or less – but Fisher was the first to recognize the arbitrary nature of this threshold.

A competing approach was proposed in 1928 by J. Neyman and Egon Pearson (the son of Karl). They criticized the arbitrariness in Fisher's choice of the test statistic and asserted that for a rational choice of test statistic one needs not only a null hypothesis but also an alternative hypothesis, which embodies a proposition that competes with the proposition represented by the null hypothesis. They formalized the testing problem as a two decision problem. Denoting the null hypothesis by H_0 and the alternative H_1, the two decisions were represented as 'reject H_0' and 'do not reject H_0.' (The second decision was also

called 'accept H_0,' but it will be discussed below that this is an unfortunate term.) Two errors are possible: rejecting a true H_0, and failing to reject a false H_0. Neyman and Pearson conceived of the null hypothesis as a standard situation, the burden of proof residing with the researcher to demonstrate (if possible) the untenability of this proposition.

Correspondingly, they called the error of rejecting a true H_0 an error of the first kind and the error of failing to reject a false H_0 an error of the second kind. Errors of the first kind are considered more serious than errors of the second kind. The probability of – correctly – rejecting H_0 if H_1 is true, which is 1 minus the probability of an error of the second kind, given that the alternative hypothesis is true, they called the power of the test. Neyman and Pearson proposed the requirement that the probability of an error of the first kind, given that the null hypothesis is indeed true, do not exceed some threshold value called the significance level usually denoted by α. Further they proposed to determine the test so that, under this essential condition, the power will be maximal.

In the Neyman–Pearson formulation, we obtain richer results (namely, specific precepts for constructing good tests) at the cost of a more demanding model. In addition to Fisher's null hypothesis, we also need to specify an alternative hypothesis; and we must conceive the testing problem as a two-decision situation. This led to vehement debate between Fisher on the one hand, and Neyman and E. Pearson on the other. This debate and the different philosophical positions are summarized by Hacking (1965) and Gigerenzer et al. (1989), who also give a further historical account. The latter study also discusses how this controversy was resolved in the teaching and practice of statistics in the social sciences by a hybrid theory which combines elements of both approaches to testing, and which has been treated often as an objective precept for the scientific method, glossing over the philosophical controversies.

Examples of this hybrid character are that, in accordance with the Neyman–Pearson approach, the theory is explained by making references to both the null and the alternative hypotheses, and to errors of the first and second kind (although power tends to be treated in a limited and often merely theoretical way), whereas – in the spirit of Fisher – statistical tests are regarded as procedures to give evidence about the particular hypothesis tested and not merely as rules of behavior that will in the long run have certain (perhaps optimal) error rates when applied to large numbers of hypotheses and data sets. Lehmann (1993) argues that indeed a unified formulation is possible, combining the best features of both approaches.

Instead of implementing the hypothesis test as a 'reject/don't reject' decision with a predetermined significance level, another approach often is followed: to report the p-value or significance probability, defined as the smallest value of the significance level at which the observed outcome would lead to rejection of the null hypothesis. Equivalently, this can be defined as the probability, calculated under the null hypothesis, of observing a result deviating from the null hypothesis at least as much as the actually observed result. This deviation is measured by the test statistic, and the p-value is just the tail probability of the test statistic. For a given significance level α, the null hypothesis is rejected if and only if $p \leq \alpha$.

Hypothesis Tests in Empirical Research

The Role of the Null Hypothesis

In the social and behavioral sciences, the standard use of hypothesis testing is directed at single research questions, practically always fragments of larger investigations, about the existence of some or other effect. This effect could be a difference between two group means, the effect of some explanatory variable on some dependent variable as expressed by a regression coefficient in multiple linear regression analysis, etc. Expressed schematically, the researcher would like to demonstrate a research hypothesis which states that the effect in question, indeed, exists. The negation of this hypothesis, then, is understood as the proposition that the effect is absent, and this proposition is put up as the null hypothesis. The research hypothesis, stating that the effect exists, is the alternative hypothesis. Rejecting the null hypothesis is interpreted as support for the existence of the hypothesized effect. In this way, the burden of proof rests with the researcher in the sense that an error of the first kind is to state that there is evidence supporting the existence of the effect if, in reality, the effect is absent. The usual welcoming phrase for the rejection of the null hypothesis is the statement that a significant result has been obtained.

Example: The *t*-test

Consider, as a major example, the proposition that two groups, arbitrarily labeled A and B, are different with respect to some numerical characteristic X. Available data are measurements X_{Ai} of this characteristic for some individuals i in group A and measurements X_{Bi} of the characteristics for other individuals i in group B. The first step in modeling this is to consider the observed values X as outcomes of random variables, usually with the assumption that they are stochastically independent and have a probability distribution not depending on the individual i. The next step is, usually, to focus on the expected values, i.e., population means in the two groups, denoted here by μ_A and μ_B. The tested proposition is formalized as the statement that μ_A and μ_B are different (two-sided alternative hypothesis) or as the statement that one (e.g., μ_A) is bigger than the other (e.g., μ_B) (one-sided alternative hypothesis). The null hypothesis H_0 is defined as the statement that μ_A and μ_B are equal.

The most commonly used test for this testing problem is *Student's t-test*, called after the pseudonym of W. Gosset, who laid the mathematical basis for this test in 1908. The test statistic is

$$T = \frac{M_A - M_B}{\sqrt{\left(\frac{1}{n_A} + \frac{1}{n_B}\right) S^2}}$$

where M_A and M_B are the two sample means, S^2 is the pooled within-group variance, and n_A and n_B are the two sample sizes. (Definitions of these quantities can be found in any statistics textbook.) This formula illustrates the property of many test statistics that an observed effect (here the difference between the two sample means) is compared to a measure of variability (based here on the within-group variance). Student/Gosset showed that, if the variable X has a normal distribution with the same variance in the two groups, then T has, if the

null hypothesis is true, the so-called t distribution on $df = n_A + n_B - 2$ degrees of freedom. For the two-sided alternative hypothesis, H_0 is rejected for large values of the absolute value of T, for the one-sided hypothesis H_0 is rejected for large values of T itself. The threshold beyond which H_0 is rejected is called critical value, and is determined from the t-distribution in such a way that the significance level has the pre-assigned value. The one-sided threshold at significance level α is denoted $t_{df;\,\alpha}$, so that the 'rejection region' for the one-sided t-test is given by $\{T > t_{df;\,\alpha}\}$. The power of the one-sided test is larger than that of the two-sided test for $\mu_A > \mu_B$ (corresponding to the one-sided alternative hypothesis) and smaller for $\mu_A < \mu_B$. This is, in the Neyman–Pearson formulation, the reason for using the one-sided test if the alternative hypothesis is one-sided (in which case parameter values $\mu_A < \mu_B$ are not taken into consideration).

The conventional value of the significance level in the social and behavioral sciences is 0.05. For large values of the combined sample size $n_A + n_B$, the critical value of the t-test approximates the critical value that can be computed from the standard normal distribution. This is because the fact that the variance is estimated and not known beforehand becomes less and less important as the combined sample size gets larger; if the population variance was known beforehand and substituted for S^2, the test statistic would have the standard normal distribution, and the test would be the so-called z-test. For this test, the critical value is 1.645 for the one-sided test and 1.960 for the two-sided test. The power depends on many quantities: the sample sizes, the population means and variances, and the significance level. As examples, the power of the one-sided z-test for $\alpha = 0.05$ is equal to 0.50 for

$$\frac{\mu_A - \mu_B}{\sigma} = 1.645\sqrt{\left(\frac{1}{n_A} + \frac{1}{n_B}\right)}$$

where σ is the within-group standard deviation. The power is equal to 0.95 if $(\mu_A - \mu_B)/\sigma$ is equal to twice this value.

The Role of Assumptions

The probability statements that are required for statistical tests do not come for free, but are based on certain assumptions about the observations used for the test. In the two-sample t-test, the assumptions are that the observations of different individuals are outcomes of statistically independent, normally distributed, random variables, with the same expected value for all individuals within the same group, and the same variance for all individuals in both groups. Such assumptions are not automatically satisfied, and for some assumptions it may be doubted whether they are ever satisfied exactly. The null hypothesis H_0 and alternative hypothesis H_1 are statements which, strictly speaking, imply these assumptions, and which therefore are not each other's complement. There is a third possibility: the assumptions are invalid, and neither H_0 nor H_1 is true. The sensitivity of the probabilistic properties of a test to these assumptions is referred to as the lack of robustness of the test. The focus of robustness studies has been on the assumptions of the null hypothesis and the sensitivity of the probability of an error of the first kind to these assumptions, but studies on robustness for deviations from assumptions of the alternative hypothesis have also been done, cf. Wilcox (1998).

One general conclusion from robustness studies is that tests are extremely sensitive to the independence assumptions made. Fortunately, those assumptions are often under control of the researcher through the choice of the experimental or observational design. Traditional departures from independent observations are multivariate observations and within-subject-repeated measures designs, and the statistical literature abounds with methods for such kinds of dependent observations. More recently, methods have been developed for clustered observations (e.g., individual respondents clustered within groups) under the names of multilevel analysis and hierarchical linear modeling.

Another general conclusion is that properties of tests derived under the assumption of normal distributions, such as the t-test, can be quite sensitive to outliers, i.e., single, or a few, observations that deviate strongly from the bulk of the observations. Since the occurrence of outliers has a very low probability under normal distributions, they are 'assumed away' by the normality assumption. The lack of robustness and sensitivity to outliers have led to three main developments.

First, there are nonparametric tests, which do not assume parametric families of distributions (such as the normal). Most of these are based on the ranks of the observations rather than their numerical values. They are standard fare in statistical textbooks. Second, robust tests have been developed, based on numerical values of the observations, which are less sensitive to outliers or heavy-tailed distributions, e.g., by some kind of automatic downweighting of outlying observations (e.g., Wilcox, 1998). The purpose of such tests is to retain a high power as much as possible while decreasing the sensitivity to deviations from the normal distribution or to departures from other assumptions.

Third, diagnostic means have been developed to spot single observations, or groups of observations, with an undue influence on the result of the statistical procedure (e.g., Cook and Weisberg, 1999; Fox, 1991). The idea behind most of these diagnostics is that most of the observations come from a distribution which corresponds well enough to the assumptions of the statistical model, but that the observations could be contaminated by a small number of poorly fitting observations. Ideally, these observations should also be recognizable by close inspection of the data or data collection process. After deleting such poorly fitting observations, one can proceed with the more traditional statistical procedures, assuming that the remaining data do conform to the model assumptions.

Confidence Intervals

Confidence intervals are closely related to hypothesis tests. They focus on a parameter in the statistical model. Examples of such parameters are, in the two sample situation described above, the difference of the two population means, $\mu_A - \mu_B$, or the within-group standard deviation, σ. To frame this in general terms, consider a one-dimensional statistical parameter denoted by θ. A null hypothesis test is about the question whether the data is compatible with the hypothesis that the parameter θ (in this case μ_A–μ_B) has the particular value 0. Instead, one could put forward the question: what are the values of θ with which the data is compatible? This question can be related to

hypothesis testing by considering the auxiliary problem of testing the null hypothesis $H_0{:}\theta = \theta_0$ against the alternative hypothesis $H_1{:}\theta \neq \theta_0$, for an arbitrary but fixed value θ_0. The data may be said to be compatible with any value of θ_0 for which this null hypothesis would not be rejected at the given level of significance. Thus, the confidence interval is the interval of non-rejected null hypotheses.

Another way of viewing the confidence interval is as follows. A confidence coefficient $1 - \alpha$ is determined by the researcher (a conventional value is 0.95). The confidence interval is an interval with lower boundary L and upper boundary U, calculated from the data and therefore being random variables, with the property that the probability that $L \leq \theta \leq U$, i.e., the interval contains the true parameter value, is at least $1 - \alpha$. It can be proved mathematically that the interval of non-rejected null hypotheses has precisely this property.

The confidence interval can be inverted to yield a hypothesis test for any null hypothesis of the form H_0: $\theta = \theta_0$ in the following way. For the most usual null hypothesis that $\theta = 0$, the hypothesis is rejected if the value 0 is not included in the confidence interval. More generally, the null hypothesis $H_0{:}\theta = \theta_0$ is rejected whenever θ_0 is outside the confidence interval. This shows that a confidence interval is strictly more informative than a single hypothesis test.

Problems in the Interpretation and Use of Hypothesis Tests

While hypothesis tests have been applied routinely by hosts of social and behavioral scientists, there have been continuing debates, sometimes vehement and polemic, about their use, among those inclined to philosophical or foundational discussion. Many contentious issues can be found in Harlow et al. (1997), Nickerson (2000), and Wilkinson and TFSI (1999). Within the context of the present contribution, I can only give a personally colored discussion of some main points which might contribute to a better understanding and a more judicious application of hypothesis tests.

The reason that there has been so much criticism of the nature and use of hypothesis tests, is in my view the difficulty of reasoning with uncertain evidence and the natural human tendency to take recourse to behavioral rules instead of cogitate afresh, again and again, about how to proceed. The empirical researcher would like to conclude unequivocally whether a theory is true or false, whether an effect is present or absent. However, experimental and observational data on human behavior are bound to be so variable that the evidence produced by these data is uncertain. Our human tendency is to reason – if only provisionally – as if our conclusions are certain rather than tentative; to be concise rather than accurate in reporting our arguments and findings; and to use simple rules for steering how we make inference from data to theories. We are tempted to reason as if '$p > \alpha$' implies that the investigated effect is nil, and the presumed theory is false, while '$p \leq \alpha$' proves that the effect indeed exists and the theory is true.

However, such cognitive shortcuts amount to serious misuse of hypothesis testing. Much of the criticism of the use of hypothesis testing therefore is wellfounded. In my view, this implies that better interpretations of hypothesis testing should be promoted, and that tests should be used less mechanically and combined with other argumentations and other statistical procedures. In any case, the user of tests (or other statistical procedures) should realize that these procedures are based on the assumption that there is random variability in the data which cannot be completely filtered out of the results. Whether a test result is significant or not depends partly on chance, and each researcher obtaining a significant result should be aware that this could be an error of the first kind, just as a non-significant result could be an error of the second kind.

Some Misinterpretations

The following list tries to correct misinterpretations that have haunted applications of statistical tests. A more extensive discussion can be found, e.g., in Nickerson (2000).

a. A common misinterpretation is that non-rejection implies support for the null hypothesis. Non-rejection should be interpreted, however, as an undecided outcome: there is not enough evidence against the null hypothesis, but this does not imply that there is evidence for the null hypothesis. Maybe the sample size is small, or error variability is large, so that the data does not contain much information anyway. Usually, the alternative hypothesis contains probability distributions that approximate the null distribution; e.g., when testing $\mu_A - \mu_B = 0$ against $\mu_A - \mu_B \neq 0$, the difference between the two population means can be tiny, while the alternative hypothesis is still true. In other words, the power of practically all tests is quite low in a sizeable part of the alternative hypothesis, so if one of the distributions in this part would prevail, chances would be low of rejecting the null hypothesis. Therefore, non-rejection provides support for those parts of the alternative practically as strongly as for the null hypothesis itself, and non-rejection may not be interpreted as support for the null hypothesis and against the alternative hypothesis.
b. If one wishes to get more information about whether a nonsignificant result provides support for the null hypothesis, a power study is not the answer. Statistical power is the probability to reject the null hypothesis, if a given effect size obtains. Its interpretation cannot be inverted as being the degree of support of the null hypothesis in the case of nonsignificance. Power studies are important in the stage of planning a study. Once the study has been conducted, and one wishes to see in more detail to what extent the null and alternative hypotheses are supported, a confidence interval is the appropriate procedure (also see Wilkinson and TFSI, 1999, p. 596).
c. Test results tell us nothing about the probabilities of null or alternative hypothesis. The probabilities known as the significance level or the power of the test are probabilities of certain sets of outcomes given the condition that the null or, respectively, the alternative hypothesis is true.
d. A significant result is not necessarily important. Very low p-values do not in themselves imply large effect sizes. A small estimated effect size still can yield a low p-value, e.g., if the corresponding standard error is very small, which can be caused by a large sample or by good experimental

control. Investigation of effect sizes is important, and is a different thing than hypothesis testing. The importance of reporting effect sizes is stressed in Schmidt (1996) and Wilkinson and TFSI (1999).

e. The alternative hypothesis is not the same as a scientific theory. If a researcher is investigating some theory empirically, this can be based on tests of which the alternative hypotheses are deduced from the theory, but always under the assumption that the study was well designed and usually under additional technical assumptions such as, e.g., normality of the distributions. Since the alternative hypothesis is only a consequence and not a sufficient condition for the theory, it is possible that the alternative hypothesis is true but the theory is not. To find support for theories, one has to find corroborations of many consequences of the theory under various circumstances, not just of one of its implications. On the other hand, it is possible that the theory is true but the alternative hypothesis deduced from it is not, e.g., because the experiment or observation was ill designed or because the auxiliary technical assumptions are not satisfied.

f. The null hypothesis is just what it says: a hypothesis. The test is not invalidated by the mere fact that there are other reasons for thinking, or knowing, that the null hypothesis is wrong. Even if there may be other reasons for which the null hypothesis is wrong, still it can be sensible to check whether the data at hand are, or are not, compatible with it.

Limitations of the Neyman–Pearson Approach to Hypothesis Testing

The Neyman–Pearson (1928) formulation changed the concept of hypothesis testing because it provided a rational basis for the choice of a test statistic. This was obtained at the cost of a quite narrow frame for the notion of a hypothesis test: a two-decision problem in which one error ('type I') is considered much more serious than the other error ('type II'). This model for decision-making is often inappropriate and, when it is useful, it is more commonly a useful approximation than a faithful representation of the actual decision situation. Some of its limitations are discussed briefly in this section.

a. Even when a dichotomous decision must be taken as a result of a scientific investigation, it is possible that both types of error should be considered equally serious. This is the case, e.g., when two therapies are compared and the most promising one must be chosen for further study or for practical application. If the costs of both kinds of error (choose therapy B, while A is better; or choose therapy A, while B is better) are about the same, then there is no asymmetry between the two competing hypotheses, and a significance test is not in order.

b. Often there are more than two outcomes of the decision situation. For example, in the two-sample situation discussed above, where the population means are μ_A and μ_B, and where the researcher entertains a theory implying that $\mu_A > \mu_B$, it is natural to define three decision outcomes defined as '$\mu_A > \mu_B$ (support for the theory),' 'undecided,' and '$\mu_A < \mu_B$ (evidence against the theory).' Usually, however, such a situation is represented by a Neyman–Pearson testing problem with null hypothesis H_0:'$\mu_A = \mu_B$.' and alternative H_1:'$\mu_A > \mu_B$'. If the t-statistic for $\mu_A - \mu_B$ yields a strongly negative outcome ('significance in the wrong direction') then the researcher only concludes that the null hypothesis is not rejected, whereas the data conveys the message that the alternative hypothesis should be rejected. The data then have to be considered as evidence against the theory embodied in H_1. Such a three-decision formulation is closer to the actual purpose of hypothesis tests in many situations where a one-dimensional parameter is being tested, cf. Leventhal (1999).

c. The Neyman–Pearson approach is formulated as if the data at hand is the only evidence available about the null and alternative hypotheses: it is an *in vacuo* formulation. This is almost never realistic. Often the propositions under study are theoretically plausible or implausible, there is earlier empirical evidence, there may be converging evidence (as in the case of triangulation studies) in the same investigation, and other evidence may become available in the future. In the light of this surrounding evidence, it is unrealistic – perhaps arrogant – to presume that the researcher has to take either of two decisions: 'reject H_0' or 'do not reject H_0.' It is more realistic to see the data at hand as part of the evidence that was and will be accumulated about these hypotheses. This is a major reason why presenting the result of the test as a p-value is more helpful to other researchers than presenting only the 'significant–nonsignificant' dichotomy (also see Wilkinson and TFSI, 1999).

There are several ways in which the results obtained from the data at hand, perhaps summarized in the p-value, can be combined with other evidence. In the first place, an informal combination can be and often will be made by a sensible, nonformalized weighing of the various available pieces of evidence. One formal way ofcombining evidence is provided by the Bayesian paradigm (e.g., Gelman et al., 1995). This paradigm presupposes, however, that the prior and current ideas of the researcher about the plausibility of all possible values of the statistical parameter under study be represented in a probability distribution for this parameter, a very strong requirement indeed. Other formal ways of combining evidence have been developed and are known collectively by the name of *meta-analysis* (e.g., Cook et al., 1992; Schmidt, 1996). These methods require that the several to-be-combined hypothesis tests address the same substantive hypothesis, or that they can be regarded as tests of the same substantive parameter.

Conclusion

The statistical hypothesis test is one of the basic elements of the toolbox of the empirical researcher in the social and behavioral sciences. The difficulty of reasoning on the basis of uncertain data has led, however, to many misunderstandings and unfortunate applications of this tool. The Neyman–Pearson approach is a mathematically elegant formulation of what a hypothesis test could be. Its precise formulation rarely applies literally to the daily work of social and behavioral scientists, very often it is a useful approximation to a part of the research question, sometimes it is inappropriate – but sacrosanct it is not. A

hypothesis test evaluates the data using a test statistic set up to contrast the null hypothesis with the alternative hypothesis, and the *p*-value is the probability to obtain, *if* the null hypothesis is true, outcomes of the test statistic that are at least as high as the outcome actually observed. Low values therefore are evidence against the null hypothesis, contrasted with the alternative hypothesis. It is more conducive to the advance of science to report *p*-values than merely whether the hypothesis was rejected at the conventional 0.05 level of significance.

In the interpretation of test outcomes, one should be aware that these are subject to random variability; and that the probability calculations are based on assumptions which may be in error. Incorrect assumptions can invalidate the conclusions seriously. Nonparametric and robust statistical procedures have been developed which depend less on these kinds of assumption, and diagnostics have been developed for checking some of the assumptions. When reporting empirical results, it is usually helpful to report not only tests but also estimated effect sizes and/or confidence intervals for important parameters. To sum up: 'It seems there is no escaping the use of judgment in the use and interpretation of statistical significance tests' (Nickerson, 2000, p. 256).

Abstract

Standard procedures for controlling error rates of statistical inferences assume that only a single inference is drawn from the analysis of a body of data. When an investigation yields a multiplicity of inferences, an adjustment of the error rates from standard procedures is required. Here we distinguish between two forms of multiplicity, 'multiple determination' and 'multiple comparisions.' For both, we set forth techniques for the control of a particular error rate; the rate of false discoveries (as proposed by Benjamini & Hochberg). The techniques are illustrated by applying them to state-by-state results from the National Assessment of Educational Progress. Extensions are discussed, with special attention to whether levels of the independent or classification variables should be considered 'fixed,' 'variable,' or neither.

Standard procedures for controlling the probability of erroneous statistical inferences apply only for a single comparison or determination from a given set of data. Multiplicity is encountered whenever a data analyst draws more than one inference from a data set. With multiplicity, standard procedures must be adjusted for the number of comparisons or determinations that actually or potentially are performed. If some adjustment is not made, the probability of erroneous inferences can be expected to increase with the degree of multiplicity. In other words, the data analyst loses control of a critical feature of the analysis.

Questions arising from problems of multiplicity raise a diversity of issues, issues that are important, difficult, and not fully resolved. This account emphasizes the issues, tries to avoid being trapped in undue detail, and provides examples of the application of a recommended procedure.

It is helpful to recognize several general guidelines:

a. Two approaches to the same data, with different purposes or with different questions being posed, need not yield compatible results.
b. Exact equality of long-run values is very rare and should not play an appreciable role either in one's thinking or one's practice.
c. When posing questions about data, greater realism will be very valuable.
d. The situations faced must not be characterized either as completely 'fixed' or completely 'random.'
e. In selecting a bouquet of techniques for the next decade or the next millennium, the selection must not be cast in stone; further evolution is to be expected (in later months, years, or centuries).

Issues of multiplicity appear in a wide variety of settings, including

a. outcomes, each measured with variability, in several situations:
   1. comparison of all pairs of situations ('multiple comparisons'); and
   2. comparison between each situation and a standard ('multiple determination');
b. selection of one or more elements from a set of alternatives:
   1. selection of how variables are to be expressed for analysis (i.e., what re-expression, if any, should be used?);
   2. selection of which of the available variables are to participate in an analysis (subset selection); and
   3. reduction in size of a set of alternatives in an attempt to reduce their number without losing the best.

Illustrative Settings, Error Rates, and Procedures

Some important issues arise for all of these alternatives. These issues are considered and illustrated for one example of multiple determination and one example of multiple comparisons.

Consider k independent estimates $\bar{y}_1, \bar{y}_2, \ldots, \bar{y}_k$ of, respectively, μ_1, $\mu_2, \ldots$, μ_k and an estimate of variability applicable to all these estimates. This is typical enough of multiplicity problems to render conclusions that are broadly helpful.

Multiple Determination

Defining a standard, λ, and for each μ_i, drawing conclusions about $\mu_i - \lambda$ based on $\bar{y}_i - \lambda$ is, by definition, making a multiple determination. (In some applications, μ_i is a mean change from one time to another. Often in that case, $\lambda = 0$.) Experience and common sense suggest strongly that μ_i and λ are certain to differ in some decimal place, so that a focus on a null hypothesis that $\mu_i = \lambda$ is quite unrealistic and misleading.

With an interest in $\mu_i - \lambda$ for each value of i, it is reasonable to ask for one of these conclusions: (1) to act as if $\mu_i < \lambda$; (2) to act as if the sign of $\mu_i - \lambda$ is not (yet) determined; or (3) to act as if $\mu_i > \lambda$. Here (1) or (3) is a 'definite' result, while (2) is 'indefinite.'

[†] Deceased.

Multiple Comparisons

Consider the $k(k-1)/2$ individual pair-wise comparisons $\gamma_i - \gamma_j$. Using these to draw conclusions about the set of $\mu_i - \mu_j$ is, by definition, making multiple comparisons, although the definition is more general, and applies to any set of linear contrasts among the μ_i. Because μ_i and μ_j are certain to differ in some decimal place, there is no good reason to focus on the null hypothesis that $\mu_i = \mu_j$. Instead, it should be asked, for each (i,j) pair, whether one should (1) act as if $\mu_i < \mu_j$; (2) act as if the sign of $\mu_i - \mu_j$ were not (yet) determined; or (3) act as if $\mu_i > \mu_j$.

In General

Notice the use of '>' or '<' and the avoidance of '=' and '≠.' 'Accepting the null hypothesis' is usually at best misleading. Confounding '>' and '<' as '≠' is unresponsive and confusing. Thus, focusing on direction is important when dealing with only one comparison (or determination), and becomes vital when dealing with several or many comparisons.

In these formulations, an 'error' is asserting one direction when the (unknown) truth is the other direction. (One should forget about the 'null case' of equality.) Asserting that the direction is not yet established may be a wasted opportunity, but is not an 'error.' The task is to control error while minimizing wasted opportunity, i.e., minimizing indefinite results.

Two classical choices for controlling errors consider expected error rates over replications of the study. (See, for example, Hochberg and Tamane, 1987: 7.) They are:

$$E\left\{\frac{\text{number of errors}}{\text{number of comparisons}}\right\} \leq 0.025$$

('individual,' 'unadjusted,' or 'per comparison')

and

$$E\left\{\frac{\text{number of errors}}{\text{number of families}}\right\} \leq 0.025$$

('simultaneous,' 'Bonferroni,' or 'per family').

Here, 0.025 could easily be replaced by another choice. (For consistency with commonly used notation, the chosen value will be denoted by $\alpha/2$.) 'Family' refers to an identified set of comparisons whose simultaneous error rate is to be controlled. Normally, 'number of families' would be taken equal to unity. These two choices for controlling errors differ by a factor of k for multiple determinations and of $k(k-1)/2$ for multiple comparisons, so the difference between the two can be quite large.

There has been a feeling for decades (e.g., Tukey, 1994/1953) that 'individual' or 'unadjusted' is too soft while 'simultaneous' is too severe. More recently, Benjamini and Hochberg (1995) introduced a compromise that is receiving increasing acceptance.

The two parts of their innovation are a definition of an alternative error rate, the false discovery rate (*FDR*), and a moderately simple procedure that, under the simplest circumstances, controls the *FDR*. The definition is the expectation of the ratio of the number of erroneous assertions of direction to the total number of assertions of direction, i.e.,

$$\text{false discovery rate} = \text{FDR} = E\left\{\frac{\text{number of errors}}{\max\{1,\ \text{number of definite results}\}}\right\}$$

Let p_{crit} be the tail area (usually for each of two tails) of the null sampling distribution of the test statistic for any single comparison being judged by a multiplicity-respecting procedure. Each such procedure will stipulate a probability of error or average fraction of error that is bounded by $\alpha/2$ when judging confidence of direction. The value of p_{crit} will depend on the sort of confidence to be attained. Let K be the number of determinations or comparisons in the family under consideration, where $K = k$ for multiple determinations and $K = k(k-1)/2$ for all pair-wise multiple comparisons. Let $h = 1, \ldots, K$ be the rank of the p-value associated with the test statistic for the comparison concerned when ordered from smallest to largest, so that the observed p-values – $p_{(h)}$ for the hth comparison – are weakly increasing from $h = 1$ to $h = K$. Three distinct procedures, two classical choices and one that controls the *FDR*, are defined as follows:

Unadjusted: be confident of the observed direction for comparison h if

$$p_{(h)} \leq p_{\text{crit}} = p_{UNA} = \alpha/2$$

FDR (Benjamini and Hochberg, 1995): be confident of the observed direction of the hth comparison when $p_{(h)}$ is the largest p-value such that

$$p_{(h)} \leq p_{\text{crit}} = p_{\text{B-H}}(h) = (h/K)\alpha/2.$$

Moreover, be confident of the observed direction for all comparisons g with

$$p_{(g)} \leq p_{(h)}, \text{i.e.}, g = 1, \ldots, h.$$

Bonferroni (per family): be confident of the observed direction for comparison h if

$$p_{(h)} \leq p_{\text{crit}} = p_{BON} = (1/K)\alpha/2.$$

Because

$$(1/K) \leq (h/K) \leq 1$$

it must be true that

$$p_{BON} \leq p_{\text{B-H}}(h) \leq p_{UNA}$$

Specifically, $p_{\text{B-H}}(h) = (h)p_{BON}$ and $p_{UNA} = (K)p_{BON}$. The three collections of confident directions corresponding to these three approaches are nested, with the collection for the unadjusted procedure the largest and that for the Bonferroni the smallest.

Examples: The NAEP Trial State Assessment

Data from the National Assessment of Educational Progress (NAEP) Trial State Assessment were subjected to two separate analyses by Williams et al. (1999). The data for the first analysis consist of average eighth-grade mathematics proficiency scores for the 34 states that participated in both the 1990 and 1992 NAEP assessments; data for the second analysis consist of average eighth-grade mathematics proficiency scores for the 41 states that participated in 1992 (Johnson et al. 1993).

Multiple Determination

One way of assessing year-to-year change in state mathematics achievement involves directly testing the significance of change

in each of the 34 states. An ordinary Bonferroni adjustment for control of Type I error per family, as was used by NAEP (Johnson et al, 1993), results in an effective critical *p*- value of $p_{BON} = 0.000\,735$ for $\alpha/2 = 0.025$. Table 1 contains the computed difference between 1990 and 1992 mathematics achievement means for each state and the computed pooled standard error. It also includes the statistical decision about confidence in direction (with confident direction indicated by '*b*' in each column) for each state under the three multiplicity treatments. For this example, critical *p*- values are used as a basis for comparison of the adjustment procedures. The cutoff critical *t* value for each procedure is also displayed in the bottom line of Table 1.

The unadjusted per comparison approach is confident about the direction of 15 differences, whereas the Benjamini–Hochberg (B–H) *FDR* procedure is confident about 11 of these, and the Bonferroni technique is confident about the direction of only four of the differences.

Multiple Comparisons

All pair-wise mean differences between the states' 1992 eighth-grade mathematics achievement scores were considered. Because 41 states participated in the 1992 assessment, the family size is $K = 41 \times 40/2 = 820$ comparisons. Using the Bonferroni adjustment, there are 480 confident directions between states, and the use of the B–H technique results in an additional 159. The unadjusted analysis increases the number of confident directions beyond the B–H technique by only six.

For Both Examples

For each example above, the B–H *FDR* procedure has led to a greater number of confident directions than the Bonferroni procedure. For the examples, we may expect that no more than 0.025 of the confident directions identified by the B–H

Table 1 Mean eighth-grade mathematics achievement change, 1990 to 1992 (and standard error), by state, and *t*, *p*- value, and p_{crit} values for three multiple comparison adjustments, $k = 34$[a]

[b]Confident direction of change.

procedure are in error. (This is what it means to control the *FDR*.) As is generally the case, the relative advantage of the *FDR* procedure becomes greater with increasing numbers of comparisons (Kesselman et al. 1999).

General Considerations

Qualitative Status

In a situation where only a very few of the results are definite, the B–H false discovery procedure performs much like the Bonferroni simultaneous approach. Because these situations include those where 'definite' is purely accidental, as in extreme instances of 'data mining,' it is important that the approach selected resembles a severe procedure, and the *FDR* approach does so.

In a situation where the total number of definite results is a large fraction of the total number of comparisons an algorithm that controls the *FDR* behaves like the unadjusted procedure. If many comparisons deserve a definite result, it is reasonable that the selected approach should not lead to excessively many errors, and again, the *FDR* approach satisfies the criterion.

Family Size

One of the many problems associated with multiplicity is a frequent strong dependence of result on the number of comparisons in the family. Applying 'simultaneous' to Vermont vs. Maine as New England states can give results fairly different from applying it to Vermont vs. Maine as two of the 'lower 48,' with a family more than 75 times as large in the latter case. Controlling *FDR* turns out to be much less dependent on family size than the use of simultaneous control.

If the individual elements, e.g., the individual determinations, are stochastically independent, then it is known (Benjamini and Hochberg, 1995) that using the *FDR* algorithm does control the rate of false discoveries, and may be unnecessarily conservative. It is reasonable to believe that the result of applying the *FDR* algorithm to elements lightly correlated in the sort of way arising from multiple comparisons will be even more conservative.

For making multiple comparisons in the special case where the true values follow an idealized Gaussian distribution, simulations have shown (Lewis and Tukey, 2001) that the algorithm can be made less conservative while still protecting the rate of false discoveries, at least when the number of values being compared is no greater than 25. The modified algorithm follows the B–H approach, but uses $(h/k)\sqrt{(h+1)/2}$ in place of (h/K) in the formula for $p_{\text{B–H}}(h)$, with a caveat that enlargement should stop when the raw modification would otherwise be more liberal than the unadjusted analysis. This modification, here denoted by 'TSR,' results in the following expression for the series of critical values:

$$p_{TSR}(h) = \min\left\{1, (h/K)\sqrt{(h+1)/2}\right\}(\alpha/2)$$

Simulations indicate that a substantial improvement in power may be attained with this modification to the B–H procedure in the situations for which it is appropriate.

For additional recent work on procedures that control the *FDR*, see Shaffer (1999) and Benjamini and Hochberg (2000).

'Fixed' and 'Variable'

A major source of debate associated with multiplicity and factorial design has to do with 'fixed' vs. 'variable,' i.e., fixed versus random. A significant part of the confusion and conflict can be traced to an unwarranted belief, in tests of hypotheses, that mean squares themselves (or what mean squares estimate) are important. With interest just in directionality, each of the individual questions and answers in multiple comparisons involve $\bar{y}_i - \bar{y}_j$, where i and j are specified, and there is *no sense in asking* whether i and j are fixed or variable. (It may make sense, as shown below, to ask if something else is fixed or variable.)

A Prototype

The simplest multiple-comparison situation that illustrates the issues is a two-way table of responses with some replication in the cells and questions directed to differences between rows. Starting with k rows and m columns, each comparison involves only two rows. Replacing two rows of measurements by one row of estimated differences yields a 1-by-m table with some replication. (Readers may choose their favorite identities for rows and for columns; in particular, COLUMNS = blocks and ROWS = varieties or treatments gives appropriate realizations.)

If the columns and calculations are fixed, then the uncertainty about the answer is a consequence of whatever makes replicates within a cell different. An estimate of the corresponding variance is, say, an f-error term.

If the columns or calculations would be different were the data to be collected again, in particular, if different applications would require different weights, then the uncertainty about the overall results would reflect two sources of variability: whatever makes replicates differ, and the long-run differences (for a selected comparison) between one column and another.

(The second would not appear if the columns, etc., would be the same.) The resulting error term will be larger than the f-error term; just how much larger will depend on the extent to which differences in columns and calculations are reflected in the overall comparison.

In one crisply specified case where the columns are a random sample from a specifiable infinite population of columns, (and the calculations are fixed), there is a well-determined error term, say, the r-error term. Clearly

$$\text{r-error term} > \text{f-error term}$$

In practice, it is not likely to have exactly either columns and calculations fixed, or columns that constitute a simple random sample from a population.

Two alternatives, 'fixed' and 'variable,' are not enough.

A good way to provide a reasonable amount of realism is to define 'c' by

$$\begin{aligned}\text{appropriate error term} &= (c)\,[\text{r-error term}] \\ &\quad + (1-C)[\text{f-error term}]\end{aligned}$$

so that 'everything fixed' corresponds to $c = 0$ and 'random' is a particular case of $c = 1$. It pays then to learn as much as possible about values of 'c' in the real world.

Mathematization vs. Realism

Those who believe that data analysis can and should be mathematized are likely to be neither happy about the introduction of 'c' nor highly tolerant of a major role for such a quantity that is not estimable from data. When they recognize, however, that 'c' is about the data analyst or the data analyst's client – about just what question is being asked or about what is the most realistic question that can reasonably be asked – then they may be more willing to think about 'c' and even to work with its default values. Those who recognize the need for more realism today (and even more tomorrow), however, must be prepared for a growing seriousness about 'c' and a growing impact of nonzero values of 'c' on the conclusions to be drawn from the analysis of data. Some may find it useful to give 'c' a Bayesian interpretation, but this is not a necessity.

The only context in which something like being serious about 'c' has passed into a subject-matter field seems to be climatology. The usefulness of a climatological result is clearly measured by its performance over the set of years from its publication until the publication of its next revision. It will be based on what happened, quantitatively, in a set of years before its construction. Weather is a nontrivial time series (surely not a white noise), so neither $c = 0$ nor $c = 1$ can be expected to do well. Empirical study has led to using a base period for climatology of roughly the last 25 years. This is not directly related to a 'c' but is of a similar flavor.

Most data analysis intended to illuminate the real world is rather like climatology. The data, whether experimental or historical, has been collected under some circumstances and in the past, while its analysis has been carried out to estimate what will or what would happen in the future. The strength of the link from past to future is important; judging it effectively is not likely to be easy. Difficult issues need to be faced. If analyses are to be increasingly realistic, decisions about those issues will be required.

Plausible Defaults for 'c'

To begin to face the tasks, some values of 'c' can be set forth for some crudely described situations. Using such a list as a basis for choosing a 'c' in real data analyses is likely to be better than doing what has become customary, i.e., to assume either that $c = 0$ or $c = 1$. Values on this list will be likely to change over time as more is learned. (Here 'columns' refers to whatever versions are involved.)

$c = 0.0$ fixed columns and calculation
$c = 0.1$ fixed columns and somewhat variable calculation
$c = 0.5$ fixed columns and illustrative weights
$c = 1.0$ random columns and fixed weights
$c = 1.4$ somewhat illustrative columns
$c = 1.6$ illustrative columns
$c = 2.0$ very illustrative columns

For simple random sampling without replacement from a finite population, the value of 'c' is 1-(sample size)/(population size).

More Quantitative Conclusions

The focus so far has been on directionality, an appropriate focus when not dealing with crisp measurements, when the hope is to be convinced by the analysis about the definiteness of at least some directions. Especially in some branches of physical science and engineering, the appropriate interest is in the sizes of differences, sizes that may be measured to a small fraction of their nominal value. Instead of directions, the focus will then be upon confidence intervals.

If the concern really is with all the pair-wise differences among k varieties, treatments, or circumstances, or if the pair-wise differences we are concerned about are selected independently of the numbers to be differenced, the Benjamini and Hochberg approach has to regard the results for all differences as definite so that the *FDR* approach could be taken to coincide with the individual unadjusted approach.

If it really is desired to make a simultaneous statement about 'all differences' or to validate a process of focusing on the single difference or the few differences that appear to be most different from a reasonable anticipation, the only viable alternative is to take a simultaneous approach, presumably using percentage points for a Studentized-range distribution.

These two procedures need not yield compatible results. A difference may have a definite direction by *FDR* but a simultaneous confidence interval that includes long-run differences of both signs. Such incompatibility should be regarded only as evidence that the analyst needs to be clear which question is being asked. Is the analyst looking for a few definite directions (or for all the directions that can reasonably be believed to be definite) or is the interest in providing intervals covering the worst that is likely to have happened for any difference?

Other Kinds of Multiplicity

The broad issues presented here in discussing multiple determination and multiple comparisons appear in most of the other situations where multiplicity matters. Details may vary, but the broad issues are parallel. For more comprehensive treatments of multiplicity, see, for example, Miller (1981), Hochberg and Tamane (1987), and Hsu (1996).

This article is a revision of the previous edition article by R.E. Kendell, volume 10, pp. 7133–7138, © 2001, Elsevier Ltd.

Abstract

Hysteria, as a disorder, has been noted since ancient times, has been a condition difficult to understand, explain, and manage. As the ages have gone by, different explanations have been propounded, the most popular being the psychoanalytical explanations. However, the term hysteria went into disrepute and has been replaced by conversion and dissociation symptoms, which unfortunately, are rather inadequate. Hysteria is also considered a form of abnormal illness behavior, and current biological research is exploring the pathophysiology underlying hysteria. The varied presentations, course and outcome, make hysteria a rather charmingly difficult condition to treat. The revisions of the current diagnostic systems, International Classification of Diseases of the WHO, and the fifth edition of Diagnostic and Statistical Manual of mental disorders are likely to propose some clinically relevant modifications in the diagnostic criteria of what was once considered as Hysteria.

Hysteria is one of the enchanting and mysterious disorders of mind, noted since centuries, poorly understood and equally difficult to treat. Due to many debates and controversies, related to its name and phenomenology, the disorder has been rechristened many times. Hence, one does not often come across the term 'hysteria' in current clinical practice. The term 'hysteria' is derived from the Greek word *hystera* meaning womb, reflecting the belief of ancient Egyptian physicians that the phenomena of the disease were due to 'wandering of the womb.' Hippocrates and Galen both accepted this assumption and until the late nineteenth century, hysteria remained a disease of women and of the body (generally the nervous system). A general practitioner working in the nineteenth century described two features, which for a long time have been regarded as central to the diagnosis of hysteria. The first was that hysteria arose as a result of the effect of excess emotion on the nervous system and second, once afflicted, sufferers often stood to benefit from their ongoing illness, a concept now known as 'secondary gain' (Carter, 1853).

Hysteria became a common diagnosis, especially in young women, and often considered to be due to hereditary weakness and cultural degeneration. It was also clearly distinguished from hypochondriasis, which was thought to be more common in men, having a less sudden onset and being accompanied by anxiety and multiple somatic complaints (Crimlisk and Ron, 1999).

The idea that it was a purely psychological disorder dates from Breuer and Freud's *Studies on Hysteria* in 1896 (Breuer and Freud, 1896), which led to the psychoanalytic concept of hysteria. The demise of hysteria, in the West, was due primarily to the fact that the term came to be used in a variety of ways that were only tenuously related, namely:

1. neurological conversion symptoms;
2. psychophysiological reactions, including pain and visceral symptoms;
3. dissociative symptoms, fugues, and amnesic episodes;
4. outbreaks of mass, or epidemic, hysteria;
5. Briquet's syndrome, multiple, unexplained, somatic symptoms, and persistent dysfunction;
6. anxiety hysteria, an obsolete psychoanalytic term for phobic anxiety; and
7. a personality type assumed to be particularly susceptible to develop hysterical symptoms.

Initial Concepts of Hysteria

The concept of hysteria originated in the second millennium BC. Egyptian priest physicians attributed the paroxysmal symptoms of their female patients to wandering of the womb, and treated them either by the local application of fragrant potions to entice the uterus back to its proper station, or by the oral administration of nauseous draughts to drive it back. The European literature of the last 400 years is summarized by Merskey (1979). Thomas Sydenham was probably the first to recognize explicitly the role of emotion in the genesis of hysteria, for in 1697 he said in his *Discourse* that "The *External Causes* of this Disease are either violent motion of the Body, or more frequently vehement Agitations of the Mind by the Assaults of Grief, Anger, Fear and such like Passions." Sydenham was, of course, allowing for 'internal causes' as well, but the identification of these remained elusive. Sir Benjamin Brodie established in the 1830s that the muscles and peripheral nerves of patients with hysterical paralyses or anesthesias appeared quite normal when examined postmortem, and by the 1870s Sir James Paget was convinced that the problem was one of volition rather that of neurological pathology. Even so, the great French neurologists Charcot and Janet still assumed at the end of that century that the fundamental cause of the suggestibility and hypnotizability of hysterics was a hereditary nervous degeneration. According to the psychoanalytic theory that developed from this revolutionary treatise, hysteria was a specific clinical entity arising from sexual conflicts originating in the oedipal phase of psychosexual development. Despite the lack of supporting empirical evidence, and the wartime evidence that widespread and florid hysterical symptoms were precipitated by overwhelming stress rather than by infantile sexual experiences or fantasies, this psychoanalytic concept of hysteria remained dominant until the 1960s.

Alternative Terms for Hysteria and Its Nosological Status

For over a century, physicians have been puzzled by the varied manifestations of the condition, dismayed by its ambiguities, and challenged by the behavior associated with it. The term is now fading into history, mainly due to changes in the nosological systems, though the various syndromes it embraced still exist and still await a satisfactory explanation. The English physician Skey commented as long ago as 1867 that "One good reason that may be assigned to the persistent employment of the term Hysteria, is the difficulty of finding a substitute for it." Those objections and that difficulty have persisted ever since. The most consistent criticisms of hysteria have centered on the multiple meanings of the term and the wide variety of symptoms and behaviors to which it has been applied.

It has been reported that in clinical practice, neurologists use a wide variety of terms for diagnosing patients lacking a neurological basis for their symptoms, like: 'functional,' 'psychogenic,' and 'hysteria.' However, when talking informally, terms 'neurotic,' 'malingering,' and 'supratentorial' become more common, whereas, the terms 'somatoform' and 'conversion,' which are among the preferred official terms, were used by less than 30% of respondents in a survey (Mace and Trimble, 1991).

Due to the criticisms, the term hysteria had been discarded but most of its constituent syndromes survived, however, though with revised titles. Conversion symptoms became conversion disorder and anxiety hysteria became phobic disorder, and both were shorn of their original psychodynamic explanations. Dissociative reactions likewise became dissociative disorders. Briquet's syndrome was renamed somatization disorder, and the hysterical personality was renamed histrionic personality disorder. Mass or epidemic hysteria was not mentioned, presumably because it was assumed that each individual would be categorized separately under the appropriate syndrome. The arguments for abandoning the term 'conversion disorder' include

1. It is based on a questionable psychoanalytical concept that is only one of several competing unproven aetiological hypotheses.
2. It is not widely used by nonpsychiatrists and some assume it is not liked by patients.
3. The disorder should be viewed from a brain as well as a mind perspective, while avoiding an unhelpful brain–mind dichotomy.
4. The current 'conversion' diagnostic criteria require a psychosocial association with symptom onset, which is difficult to find in a minority of patients, and the exclusion of feigning (malingering) which is difficult, if not impossible (Reynolds, 2012).

Diagnosis and Classification

Diagnostic systems have increasingly discouraged the use of the term 'hysteria' because of its ambiguity and current systems have dropped the term altogether. The fourth edition of Diagnostic and Statistical Manual of mental disorders (DSM-IV) classified Conversion disorder, which includes motor and sensory symptoms as well as nonepileptic seizures, under somatoform disorders, whereas dissociative symptoms, such as fugue and multiple personality, come under a separate category, dissociative disorders. The International Classification of Diseases (ICD-10) has combined these two categories under neurotic, stress-related, and somatoform disorders (Crimlisk and Ron, 1999).

Conversion disorder (DSM-IV) is diagnosed when the patient presents with symptoms referred to the central nervous system for which no cause can be found despite adequate investigations, and which are presumably caused by psychological factors. In ICD-10, conversion disorder is grouped with the dissociative disorders. Dissociative disorders are classified according to the mental faculty or psychological function that is impaired. While DSM-IV provides a separate category for dissociative identity disorder and relegates trance and possession disorders to the 'not otherwise specified' category, the converse holds true in ICD-10.

Finally, depersonalization/derealization syndrome, is included as a dissociative disorder in DSM-IV (Chaturvedi and Rajkumar, 2009). Currently, the classifications of psychiatric disorders in DSM-IV and ICD-10 are both under review. In current classifications, the traditional use of the term 'hysteria,' has been replaced by 'conversion disorder,' influenced by the psychoanalytic theory of Freud, and by 'dissociative disorder,' influenced by a related analytical theory of Janet. Within a review of somatoform disorders for DSM-5, proposals have been circulated to replace the term 'conversion disorder' with 'functional neurological disorder.' Similar suggestions are being discussed for ICD-11 (Reynolds, 2012). In DSM-5, dissociative identity disorder will include reference to possession as well as identity fragmentation, to make the disorder more applicable to culturally diverse situations. Dissociative amnesia will include dissociative fugue as a subtype. A dissociative subtype of posttraumatic stress disorder (PTSD), defined by the presence of depersonalization or derealization in addition to other PTSD symptoms, is being recommended, based upon new epidemiological and neuroimaging evidence linking it to an early life history of adversity and a combination of frontal activation and limbic inhibition (Spiegel et al., 2013). Conversion disorder (functional neurological symptom disorder) is likely to remain with the somatic symptom disorders, despite considerable dissociative comorbidity. The ICD-11 is in the process of revising somatoform disorders as Bodily distress disorders, and the dissociative disorders may be subtyped as – somatoform (conversion, bodily loss of function) or psychoform (for cognitive and consciousness involvement) dissociative disorders.

Clinical Presentations

Neurological Conversion Symptoms

Muscular weakness or paralysis, affecting one, two, or all four limbs, or resulting in loss of speech; convulsions simulating epilepsy; or a loss of sensation (commonly blindness or tunnel vision, deafness, or a circumscribed loss of cutaneous sensation) assumed to depend on the psychoanalytic mechanism of conversion. As the extent of the paralysis or sensory loss reflects the patient's ideas rather than anatomical facts, and as it can

often be demonstrated neurologically that the relevant motor or sensory pathways are undamaged, the diagnosis of hysteria can usually be made with some confidence.

Pain and Other Bodily Symptoms

Visceral symptoms like vomiting or otherwise unexplained pain assumed to be produced by the same conversion mechanism. Unlike neurological conversion symptoms, there is usually no easy way of demonstrating that such symptoms must be psychogenic and as a result the diagnosis of hysteria remains uncertain.

Dissociative Symptoms

Episodes of amnesia, fugue states, and rare cases of multiple personality assumed, after Janet, to be based on a restriction or dissociation of consciousness. Like conversion symptoms, hysterical amnesias and fugues usually develop in highly stressful situations and have the effect of providing at least a temporary respite from that stress.

Epidemic or Mass Hysteria

Since the 'dancing manias' of fourteenth-century Europe, over 100 outbreaks of mass hysteria have been recorded, usually in schools, convents, or other communities of girls or young women, and usually at times of obvious stress (Sirois, 1974). Shared apprehensions and suggestion are clearly important as those affected are always in close contact with one another and develop almost identical symptoms. Influential members of the community are generally also the first to be affected. Mass hysteria is still observed off and on in traditional societies, in Asia and Africa, affecting groups of school children or entire village being possessed by spirits, demons, or devils.

Briquet's Syndrome

This well-defined pattern of behavior, first described by the French physician Briquet in 1859 and seen almost exclusively in young women. They repeatedly consult doctors with multiple and constantly changing somatic symptoms for which no adequate cause can be found. They also have unsatisfactory sexual lives and are prone to develop mood disturbances and conversion symptoms. This behavior persists into middle age or beyond, and as a result such women acquire voluminous medical files, have multiple abdominal and pelvic operations, and often become dependent on analgesics or tranquillizers (Guze and Perley, 1963).

The Hysterical Personality

Hysterical personality was regarded as an almost exclusively feminine condition, which was assumed to be particularly susceptible to develop conversion and other hysterical symptoms. The characteristic features are attention-seeking behavior, shallow, labile emotions, and self-centered, demanding, interpersonal behavior. A variety of tactics are used to attract and retain the attention of others, including striking or sexually provocative clothing, flirtatious behavior, flattery, dramatized accounts of their past lives or current circumstances, and extravagant gestures.

Neurobiology/Pathophysiological Mechanisms

Immunological Mechanisms

The pathophysiology of conversion symptoms indicate that women are generally at higher risk for a variety of autoimmune disorders. Recent research in psychoneuroimmunology suggests that the symptoms of conversion and somatoform disorder may be explained by the central effects of inflammatory and immune mediators that are released in response to stress. (Dimsdale and Dantzer, 2007). This model is attractive because (1) it explains the association between stress and the genesis of bodily symptoms and (2) it may account for gender differences in somatization, as women's hormonal and neurochemical milieu may make them more susceptible to develop abnormal immune activation in response to stress (Chaturvedi and Rajkumar, 2009).

Sex Hormone

The high occurrence of somatic symptoms during the premenstrual phase, pregnancy, and the menopause and the preliminary evidence that some hormonally mediated conditions, such as primary dysmenorrhea and secondary amenorrhea, are associated with psychological variables and somatization are evidences to support relation between sex hormones and somatoform or dissociative symptoms (Bitzer, 2003).

Neural Circuitry

Studies looking at cerebral activation in women with somatization showed decreased metabolism in both caudate nuclei, as well as in the left putamen and right precentral gyrus (Hakala et al., 2002). Another study found hypoperfusion in a majority of subjects, with preponderance in the right hemisphere; and right cerebellar hypoperfusion was more frequent in women than men (Garcia-Campayo et al., 2001).

Studies in conversion disorder have also demonstrated decreased activity of the primary motor or sensory cortex, and increased activation of the right orbitofrontal and cingulate cortices, as well as altered basal ganglia function(Vuilleumier et al., 2001). As all these structures are involved in sensorimotor function and are interconnected with the limbic system, further investigations would help in understanding their role in the pathophysiology of somatization, as well as the neural basis of gender differences. A role of the corpus callosum has been hypothesized, based on studies showing a larger anterior corpus callosum in subjects with high hypnotisability, a status linked to conversion (Nash, 2005).

Laterality

The observation that left-sided conversion symptoms appear to be more common has led to the idea that the nondominant hemisphere may mediate 'unconscious' processes. A functional hemispheric disconnection could, therefore, result in left-sided somatic symptoms and abnormal expression of affect (la belle indifference) in away reminiscent of the presence of anosognosia in patients with right hemisphere lesions.

Neuroendocrine Dysregulation

Preliminary evidence suggests that patients with somatization disorder, dissociative disorder, and chronic unexplained pain have dysregulation of the hypothalamic-pituitary-adrenal axis, specifically in the form of elevated cortisol levels (Allen et al., 2001).

Complex Integrative Models

Models that attempt to explain conversion and dissociation have been proposed in recent years, using various perspectives. Certain common factors noted are

1. The importance of the orbitofrontal and cingulate cortex, areas involved in the organization of behavior.
2. The role of stressful and traumatic events in early childhood.
3. The effect of these events on neurodevelopment, leading to deficits in emotional and behavioral regulation.

It seems that whatever the neural substrates of these disorders might be, early life experiences and adversities play a central role in their pathogenesis. Somatoform and dissociative disorders in women represent, par excellence, the value of a biopsychosocial approach in understanding the etiology, pathogenesis, clinical presentation, and treatment of a disorder.

Abnormal Illness Behavior

Contemporary understanding of hysterical behavior has been influenced strongly by the sociological concepts of the 'sick role' and 'illness behavior' and by learning theory, and attempts to reduce both the attractions of the sick role and influences discouraging healthy behavior now have a central role in management. This conceptual model explains the distribution of hysterical behaviors in populations, including the predominance in young women, and many other clinical observations, but it fails to account either for neurological conversion symptoms or for fugues and other dissociative phenomena. The concepts of the 'sick role' and 'illness behavior' originally formulated by Parsons (1951) and Mechanic (1962) provide the starting point for a better understanding of the problem (Pilowsky, 1969). Most illness behavior is generated by recognized disease, but substantial parts of the whole are generated either by fear of disease or by the 'positive reinforcement' provided by the rewards of the invalid role. The sick role becomes attractive only in situations in which their responsibilities are abnormally heavy (soldiers in battle, for example), or when they are in trouble (impending exams, debt, the threat of blackmail or prosecution, and so on), or when the prospect of financial gain increases the attractions of illness still further (so-called compensation neurosis). The very high incidence of hysterical phenomena in exhausted combat troops suggests that everyone is potentially capable of developing hysterical symptoms, just as they are capable of developing epilepsy, but vary in their liability to do so. This variation presumably depends partly on constitutional variables like suggestibility and capacity to dissociate, partly on past experience, and partly on the subject's current social situation.

Relevance of Hysterical Behaviors

Some of the behaviors considered diagnostic features of hysteria and conversion disorders have been found to lack the diagnostic specificity (Lazare, 1981). Secondary gain, once a key feature, has been noted in other medical disorders as well. Similarly, attention-seeking behavior is more a personality trait, nonspecific to any illness. Persons who do not receive due attention to their symptoms and suffering, try to draw attention of their health professionals. *La belle indifference* was considered diagnostic of hysteria for long, but was found to be a nonspecific feature, and a way of coping and response to stress. *La belle indifference* could also be considered as a dissociative phenomenon. There was a lack of evidence that symbolism could explain the hysterical symptoms, since the psychodynamic formulations became less popular. As mentioned above, histrionic personality does not always lead to hysterical symptoms, and persons with this personality could develop other disorders, and persons with other personality traits could develop conversion symptoms (Sharma and Chaturvedi, 1995).

Changing Epidemiology of Hysteria

Few community surveys of the incidence or prevalence of psychiatric syndromes have generated satisfactory measures of hysteria, because the range of phenomena embraced by the term is so vague and variable, and because most hysterical phenomena are short-lived. The incidence of conversion hysteria is falling both in the industrial and the developing world (in India there is epidemiological evidence of this (Nandi et al., 2000)) is probably that in both settings levels of education and sophistication are rising and life becoming less stressful. However, hysteria continues to be prevalent in developing and traditional societies, though the nomenclature has changed (Chaturvedi et al., 2010; Nandi et al., 2000). The reason hysterical symptoms are seen mainly in adolescents and young adults is probably because the adoption of a dependent role comes most readily to those who have only recently forgone the privileges of childhood and are least experienced at coping with the demands of the adult world. The frequent coexistence of hysteria and organic disease is also readily explained, for those who are genuinely ill or handicapped – by epilepsy or multiple sclerosis, for example – are the very people likely to have the most difficulty coping with the demands of everyday life, and with the most vivid and recent awareness of the rewards of the sick role. Finally, the predominance of left-sided limb paralyses and anesthesias, first remarked upon by Briquet, is explained, for in a right-handed person this minimizes the handicap without reducing the social impact.

Choice of Symptoms and Outcome

According to psychoanalytic theory, the choice of symptom is determined by its symbolic meaning for the patient, and doubtless this is sometimes so. Usually, though, it is determined by cultural expectations and the subject's own experience of illness, in themselves or others. The nurse who

develops hysterical blindness, for example, had severe conjunctivitis as a child, and the young man who loses the use of his legs had a grandfather who was housebound for years after a stroke.

Just as the development of hysterical symptoms is encouraged strongly by situations in which the balance of the advantages and disadvantages of sickness outweigh those of health, so recovery is encouraged by a reversal of that balance of advantage. This is why the symptom usually fades away if the situation that provoked its appearance resolves itself. If that situation persists, however, or if the inadequacies of the subject are paramount, the advantages and disadvantages of the chosen symptom become important. This is why disabling symptoms, like blindness or inability to stand or walk, have a comparatively good prognosis, whereas those which can be switched on or off as occasion demands, like fits or vomiting, or cause little disability, like tremors, are more intractable.

Investigation and Treatment

There are two implications for the investigation of patients with suspected hysterical symptoms, both well known. The first is that medical attention, admission to hospital, and investigations may easily potentiate the illness behavior. For this reason it is important that the investigations needed to make sure that the patient's symptoms are indeed hysterical are completed as quickly as possible, and not repeated without good reason. The second is that it is immaterial whether or not the patient is aware that he or she is in some sense feigning illness, because the treatment is the same either way. Although the dilemma usually was avoided by assuming unconscious motivation, the traditional medical or psychoanalytic approach should require a distinction between conscious motivation (which is malingering, and so subject to strong disapproval) and unconscious motivation (which is an illness – hysteria – and so worthy of sympathy and treatment) in spite of the fact that it is generally impossible to distinguish the two. Indeed, the patient's degree of awareness often varies from time to time, so that what is initially unconscious becomes conscious, and vice versa.

There are always two components to the management of hysterical symptoms: an attempt to form a psychotherapeutic relationship with the patient, and an assessment of the elements of their social environment, which are encouraging or discouraging invalid behavior. The former is never straightforward, and inexperienced therapists often allow themselves to be manipulated by flattery or coquetry, or end up angrily rejecting the patient because they resent being manipulated, or indeed do both these things in succession. Occasionally it is possible by gentle degrees to lead the patient into a discussion of the emotional predicament from which their symptoms arose, and of the relationship between that predicament and their symptoms. More often there is a sustained denial of emotional difficulties of any kind, and it becomes increasingly clear that the subject is more interested in being a patient than in being cured, and curiously uninterested in the origins of their symptoms.

Conclusions

Although this contemporary social and behavioral view of hysterical behaviors explains many otherwise puzzling clinical observations, it provides no explanation of the mechanisms of conversion and dissociation. The explanatory theories proposed originally by Freud and Janet over 100 years ago have been abandoned, but nothing has yet been offered in their place and the neurophysiology of both phenomena remains a mystery. Indeed, shorn of the original psychoanalytic assumption that unconscious anxiety was being converted into a neurological deficit, the term conversion disorder has lost all meaning. And hysteria itself has been discarded. But as Lewis (1975) observed a generation ago, "a tough old word like hysteria dies very hard." It may yet come back.

Iconicity in Linguistics

John Haiman, Macalester College, St Paul, MN, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Iconicity is a constant factor in generating linguistic 'pantomimes' of thought. Its never less constant enemies are the limitations imposed by the medium of sound itself, and the working of ritualization: routinization (or grammaticalization in the broad sense, which includes both analogy/systematization and sound change/erosion) and decorative bulking.

In spite of sound change, systematization by analogy and systematization via ritualization, iconicity survives both in linguistic form and as a productive force in language change. In fact some of the most fundamental rules and principles in language are iconically motivated. This is in spite of the majority view of students of language today: the doctrine of arbitrariness, that anything can stand for anything. Not only are words arbitrary: the universal of double articulation ensures that, at the phonological level, individual signs are associated with no meaning whatsoever. At the morphosyntactic level, a distinction may be made between the lexicon and grammar. Challenges to the doctrine of arbitrariness thus fall into three groups.

At the phonological level, the notion of sound symbolism is such a challenge. Although submorphemic constant correlations between sound and meaning are marginal in languages like English, it has been argued that they are much more pervasive in many languages of Africa and Southeast Asia. At the word level, the corresponding challenge is the notion of onomatopoeia, which has been acknowledged to be marginal in every language. In the artificial registers of poetry, the sound may indeed be made to be an echo to the sense, but this is not the case in flat-footed prose. At the level of compounds and more complex syntagms, however, diagrammatic iconicity in the sense of Peirce (1932) has always been both pervasive and acknowledged. Among the staples of linguistic theory which have been strongly iconic are

1. The doctrine of semantic compositionality or Saussure's motivation (Saussure, 1916): "The meaning of a complex expression is in some way the sum of the meanings of its parts."
2. Behaghel's first law (Behaghel, 1932: 4): "Conceptual closeness of ideas is reflected in physical closeness of their expression." One of the clearest demonstrations of this is in Bolinger and Gerstman's (1957) discussion of the contrasts between phrases like 'light housekeeper' and 'lighthouse keeper,' in which, as they demonstrated, the perceptual phonetic contrast mirrors the orthographical distinction. Other work in the same vein is Greenberg (1966b) and Bybee (1985) – restatements and elaborations of the traditional insight that derivational affixes are closer to the root than are inflectional ones; Givon (1980) – the degree of embeddedness of a complement clause is a reflection of the degree of control exerted by the subject of the containing clause; and Haiman (1985a), which surveys contrasts between direct and indirect causation, between alienable and inalienable possession, and the semantic consequences of coordination reduction.
3. Related to physical distance is the idea that the degree of physical incorporation of a string into a larger one corresponds to the degree of its conceptual incorporation in the material into the framework represented by the matrix string. Direct quotation resists incorporation into a matrix sentence, indirect quotation does not. So-called 'relevance conditionals' (e.g., "If you're hungry, there's food in the fridge") resist incorporation within a complex sentence, while ordinary conditionals do not: the former do not 'count' as constituents in V/2 languages like German (König and van der Auwera, 1988).
4. "The same form is used for the same meaning." This is the basis of grammatical analogy (Anttila, 1989: 89). The somewhat less familiar corollary, that there are no true synonyms, or that different form is a reflection of different content, is the basis for Bréal's laws of repartition and specialization (Bréal, 1897: 26), and underlies much recent work in descriptive syntax. The 'same is same' heuristic also lies behind all the (never entirely successful) attempts to construct a 'notional' definition for parts of speech and grammatical categories in general (e.g., Jakobson, 1936; Wierzbicka, 1985), as well as for attempts to find explanations for recurrent polysemy of grammatical constructions.
5. "More form reflects more meaning." This is still the most widespread diagnostic for markedness (see Greenberg, 1966a: 26–27). The clearest demonstration in typological research in Benveniste (1946) on the most frequent

expression of the third person singular. As a creative dynamic principle of perception and interpretation, the 'more is more' heuristic is identified as what has led to the frequently attested restructuring of verbal paradigms (e.g., Watkins, 1962). It is probably also what has led to the excrescence of derivational morphology in some less widely attested cases. In Khmer and in Romanian, for example, a reduced pronunciation of a verb was reinterpreted as the verb, the full form being reinterpreted as a derived nominalization or a derived causative (Haiman, 2003).

6. The order of clauses (e.g., in "I came, I saw, I conquered") corresponds to the order of events, other things being equal (Jakobson, 1965). Elaborations on this *post hoc* (*conceptually*), *ergo*, *post hoc* (*linguistically*) heuristic are to be found in the Prague School notion of 'communicative dynamism,' itself a derivative of Behaghel's recognition (1932: 4) in his second law, that the given precedes the new; Greenberg (1966b) on the order of mention of conjuncts, and of the order of protasis and apodosis; and Tai (1985) on the order of constituents within the clause. Hawkins (1994) and others have proposed that Behaghel's second law (that short constituents precede longer ones, as in Malkiel's 'irreversible binomials' (Malkiel, 1959)) may also be reducible to this principle, given the tendency to give reduced expression to what is more familiar or given (frequently old) information.
7. Conceptual symmetry is reflected in formal symmetry in both syntagms and paradigms. In a syntagm, coordinate conjunctions, reciprocals, comparisons, and correlative constructions like 'the more, the merrier' tend to be symmetrically expressed in most languages (Haiman, 1985a: 72–102). More subtly, conceptual symmetry is sometimes expressed by paradigmatic symmetry. The failure of reflexivization in sentences like "I like me" and "I want ME to stay behind" is a reflection of the loss of 'speaker privilege,' and hence, indirectly, a direct reflection of a divided self (Haiman, 1998: 77): 'me' is treated no differently from (i.e., symmetrically with) any other participant on the perceptual stage. So, too, conceptual asymmetry may be reflected in formal asymmetry. Langacker (1985) argues that the structure "there's snow all around (sc. me)" directly reflects the subject's inability to see himself, and thus reflects the asymmetry between the perceiving subject and the perceived object directly.

In spite of the opacity and arbitrariness in much of language, there is a sense in which we do not believe in our bones that it is real. In his short story 'Funes the memorious,' Borges showed what a totally arbitrary code would be:

> In place of 7,013, he would say (for example) *Maximo Perez*; in place of 7,014, *The Railroad*; other numbers were Luis Melian Lafinur, Olimar, suphur, the reins, the whale, the gas, the cauldron, Napoleon, Agustin de Vedia. In place of 500, he would say *nine* …
>
> Borges, 1964: 64

All students of language, however, committed they may be to the idea that 'anything can stand for anything,' will probably find this conception of a language to be strikingly alien. What Borges's imaginative and outrageous reduction forces us to acknowledge is the extreme unlikeliness of such willed original opacity. However opaque the signs and combinations of language may seem to us in any mature grammatical system, this system probably owes its present form to an originally iconic code like a pantomime (Donald, 1991; Fonagy, 2000), modified over the course of time.

Given the acknowledged universality of motivation, analogy, markedness, Behaghel's law, and the extreme implausibility of truly arbitrary 'languages' like the number system of Funes, the interesting question is where does arbitrariness arise? Several factors have been pointed out.

One obscuring factor is that limitations of the medium lead to competing (albeit impeccably iconic) motivations. For example, 'same form' is motivated not only by 'same meaning,' but by symmetry or 'lack of speaker privilege.' 'More form' is motivated not only by 'more meaning,' but also by 'less frequency' (Greenberg, 1966a, on the relative marking of dual and plural), 'less familiarity,' greater difficulty of recovery (Givon, 1983, on the formal bulk of nominal expressions which refer back to more or less distant antecedents), greater surprise (Haspelmath, 1993, on the relative marking of causativity versus intransitivity for inchoative verbs like *freeze* and *break*; Haiman, 1985a: 168–174; Haiman, 1998: Chapter 5, on the relative marking of coreference), and 'more politeness' ('more form' is 'more wrapping,' cf Geertz, 1960; Haiman, 1985a: 151–155). 'First mention' is motivated not only by being 'most familiar,' but also by Jespersen's (1949: 54) "principle of actuality: what is at the moment uppermost in the speaker's mind tends to be first expressed." Similarly 'element incorporation' may be iconically motivated (as is the case for indirect quotation) or economically motivated (as is the case for object incorporation of typical, or frequently occurring objects). Simple repetition may have as many as half a dozen familiar motivations (Haiman, 2014). Overburdened with too many semantic distinctions, a form may come to seem more or less arbitrary (Bolinger, 1975: 110). The first letters of the Library of Congress book cataloging system have absolute values, but the second letters, whose meanings are determined by a large number of context-sensitive rules, are thereby rendered meaningless (Haiman, 1998: 149–150). So far, the most promising demonstration of the reality of iconicity in spite of this limitation is that where there are no competing motivations for the 'limited good' of a particular formal expression, there tends to be agreement (Haiman, 1985a: Chapter 6).

Opacity or the apparent 'autonomy of syntax' can also arise as the result of a number of diachronic factors: erosion, routinization, systematization, and ritualization are perhaps the most important. We can illustrate some of these tendencies in a number system whose iconic origins are still very much in evidence – the Roman numerals.

The first three numbers are of course as iconic as a tally. The numeral V is apparently opaque, but still barely recognizable as a diagram of a human hand. The motivation for the abbreviation was probably no different from the motivation for the sound changes of truncation or assimilation: it is faster and easier to write V than to draw the hand with all five digits. The numeral X can still be seen as a combination of two V's, one on top of the other. The numbers C and M are also icons, but of a different sort: C (entum) and M (ille) are examples of

another kind of abbreviation, and illustrate competing iconic motivations coexisting within the same code.

Implicit in even the simplest compound sign, like II, is a rule which seems so natural that it is hardly recognized at first. It is that the combination XY is to be read as 'X' + 'Y.' This is as true of VI, VII, VIII, …, XXXIII, …, MMCCCVIII, as it is of II. At some point, an unknown genius recognized and applied analogical reasoning to this natural rule: if XY is read as 'X' + 'Y,' then perhaps, under some (very restricted) conditions YX could be read as 'X' − 'Y.' The result, apparent in numerals like IV, IX, XC, and the like, is motivated within the system. But these numbers, even when they are drawn in the most painstaking and redundant detail, can no longer correspond iconically to the quantities they represent. Analogy has led in this case to something that is the precise opposite of diagrammatic iconicity. The signs within a system cease to reflect reality and take on a life of their own when they are manipulated by rules internal to the system, as well as by the reality they still attempt to represent.

Within language, aspects of systematization are recognized as

1. the substitution of value for signification within a paradigm (the meaning of signs lies not in their relationship to things in the world, but in their relationship to each other, cf Saussure, 1916);
2. the analogical extension of fixed structures beyond the contexts for which they were originally motivated;
3. the existence of various kinds of context sensitivity within a syntagm (Haiman, 1998: 149–150);
4. digitization, the conversion of analogical modeling to 'all-or-nothing' representation.

A compact example of systematization in syntax is the stress pattern of thetic sentences such as 'TRUMAN died' (Lambrecht, 1988) in languages like English. A stress pattern should iconically reflect the contrast between old and new information, and a word order pattern should do the same. In English, iconic stress has led to sentences such as 'Truman DIED' where the predicate is new relative to the subject, but routinization has led to a fixed SVO word order, which is emancipated from the motivation of functional sentence perspective. Given that low stress … HIGH stress means 'predicate is new,' perhaps (by an analogical leap similar to the invention of the Roman numeral IV) HIGH stress … low stress means not only 'subject is new' (which it still iconically can do), but also 'everything is new.'

The Roman numeral system is far more iconic than the Arabic system, but it is already fully abstract and digitized. A more primitive system, corresponding to those languages in which there are no numerals higher than some 'highest digit' (frequently 2), resorts to subjective and analogic or iconic means of modeling higher numbers, typically (one, two, …, many). More languages resort to this analogical modeling in the domain of fractions and present series like (one, a half, …, a bit). The digitization process 'colonizes' the analogic domain, substituting fixed quantities for impressionistic assessments like 'many' and 'a bit.' A roughly analogous 'digitalizing colonization' process cannot be observed in the lexicon, or in morphosyntax, but it is observed in the conventionalization of intonation (Léon, 1993; Fonagy, 1971): from being a purely analogical 'more is more' system, it becomes grammaticalized and transformed into an 'all-or-nothing' system – although never completely so (Bolinger, 1961, 1986).

The familiar tension between iconicity and routinization (Haiman, 2011) is apparent in the English auxiliary system, which includes not only the modals (perfective) *have*, and (progressive and passive) *be*, but also auxiliaries like have to, be supposed to, be about to, be going to, just about, keep on, used to, would rather, had better, get to, and an indeterminate number of others. To the extent that these may co-occur, the iconic order of auxiliaries is such that each includes within its scope all of the following (auxiliary) verbs. Thus, *get to try to VP* does not mean the same as *try to get to VP* and the meaning differences in all such cases reliably obey the iconic scope rule.

What distinguishes the familiar English Chomskyan syntagm *Modal* + *Perfective* + *Progressive* + *Passive* from all other combinations of auxiliary verbs is that this order is fixed and thus not subject to scope iconicity. It is only this distinction which separates a class of what could be (falsely) called 'true (Chomskyan) auxiliaries' from all the other complement taking verbs which – irrespective of the nature of the complementizer which they assign to the following verb – occur in scope–iconic order. And even within this set, iconicity is partially maintained: both of the passive auxiliaries *be* and *get* can occur only immediately before the main verb which is within their scope. (Another putative criterion for true auxiliaryhood, the complementary distribution of the Modals, *have*, and *be* with the quasi-auxiliary verb *do* is incoherent, as is well known. By this criterion, perfective *have* is an auxiliary while obligative *have*(*to*) is not, and *be* in all of its functions, whether as a (main verb) copula, the progressive or passive auxiliary, or as part of an auxiliary as in *be going to* is an auxiliary. Only in the imperative and prohibitive, where *do* may or must co-occur with the copula, is the complementary distribution between *do* and strictly auxiliary uses of the verb *be* enforced, cf Haiman, 2010).

Grammaticalization corresponds to both routinization and systematization. Ritualization subsumes both of these factors, which tend to reduce linguistic expression, but also includes stylization, which tends to exaggerate them (in language as in nonlinguistic ritual). Decorative doubling, exemplified in symmetrical compounds like *last and final*, is one example of this semantically unmotivated (and hence noniconic) bulking. Of marginal importance in many Western languages, it is a striking feature of Khmer and other languages of Southeast Asia and elsewhere (Haiman, 2010; Williams, 2013).

Idealization, Abstraction, and Ideal Types

Abstract

Abstraction and idealization are mental processes that are employed in order to simplify and organize empirical information to enable the use of laws and models to explain that information. Ideal types are a form of idealization that have been particularly important in the methodology of the social sciences and that are associated most closely with Max Weber.

Abstraction

Abstraction is a psychological action in which usually one, but possibly more, aspect of a thing or process, or a group of things or processes, are mentally separated out from that thing or process, or group of things or processes. All intelligent thought about the sensible empirical world can be understood as being abstractive. The empirical world throws up an ever-changing mélange of details that invades our senses. To render this datum intelligible, inconvenient details and transitory changes need to be abstracted away from, and simple, stable generalizations located. The successful identification of natural and social kinds would seem to require the ability to perform abstractions. Individual police officers, who instantiate the social, kind police officer, vary considerably in personal appearance and in other forms of possible identification. In order to reliably identify an individual as a police officer, the stable and enduring underlying properties that are common to the kind police officer need to be identified.

Because the process of abstraction involves the disregarding of particular features of things or processes in an attempt to develop general concepts, abstractions are sometimes conflated with universals. However, there is no requirement that a successful abstraction need leads to the development of a concept that identifies a universal. A successful abstraction may lead to the identification of relatively invariant generalizations about a kind of thing or process that fall well short of being universally applicable. The universal is conventionally contrasted with the particular, whereas the opposite of the abstract is usually held to be the concrete.

Not everyone would accept that abstraction is as pervasive in the mental lives of individuals as has been suggested here. Plato can be interpreted as denying that the intelligibility of the sensible requires abstraction. It may appear that the mind is abstracting from the experience of concrete entities to the identification of underlying general and abstract kinds. However, Plato would argue that it is actually noticing resemblances between particular entities and the entities found within a world of perfect forms, which it was familiar with before this life. Berkeley and Hume downplay the role of abstractions in everyday thought. They object to an account of abstraction provided by Locke, holding that what cannot be separated in reality cannot be separated in the mind either (Baxter, 1997). Berkeley and Hume see no need for abstraction from the empirical, in order to render the world intelligible, because they do not allow that the sensible is distinct from the intelligible.

Whether or not Berkeley and Hume are right to reject portrayals of abstraction as being all pervasive in thought, it is clear that the process of abstraction plays a central role in the mental lives of individuals. The ability to apply the sophisticated apparatus of modern mathematics and logic to actual situations depends, inter alia, on the capacity to reason abstractly. In addition, the capacity for abstract thinking enables previously unfamiliar experiences to be rendered intelligible, by relating these to the familiar. The nineteenth century empiricist John Stuart Mill presents the example of 'South Sea Islanders,' whose only experience of four-legged animals is of hogs. The islanders are able to make sense of European talk of other four-legged animals by abstracting from the concrete example of hogs to the general concept of the quadruped (Mill, 1950, p. 299).

Idealization

Idealization is a psychological act that, while not as pervasive as abstraction in everyday thought, has been extremely important in modern scientific thinking. While abstraction only involves the mental separation of aspects of things or processes, from those things and processes, when these may not be so separable in reality, idealization, which is enabled by abstraction, involves the mental rearrangement of features of reality so as to assist in the development of explanations. A familiar idealization is the frictionless plane, used to exemplify mechanical explanations. To conceptualize the frictionless plane, real planes that have friction-causing surfaces are abstracted away from. However, frictionless planes are not merely abstractions. It is convenient to imagine things that have surfaces that are frictionless, even though it is generally accepted that all surfaces exert some friction on objects that they come into contact with, however slight. For the purposes of thought experiments, disbelief is suspended and the convenient idealized fiction of a rearranged and simplified reality, which satisfies our explanatory needs, is allowed, a reality in which a surface can come into contact with an object and exert no force of friction on that object whatsoever.

The application of scientific laws and models to real complex situations often requires considerable idealization. In order to practically apply Newtonian mechanics to predict the trajectory of a driven golf ball, the golf ball is idealized as a perfect sphere that is struck with a constant force in the direction in which it is intended to travel. Details of the shape and surface of the actual ball, which in reality will affect its trajectory, are conveniently

 http://dx.doi.org/10.1016/B978-0-08-097086-8.63031-3

ignored. Other potentially relevant causal factors such as wind resistance and humidity are also ignored. The resulting idealized calculation of the golf ball's trajectory will, at best, be approximately true some of the time. The trajectory of a golf ball that is hooked or sliced will not be accurately predicted, nor will the trajectory of an irregularly shaped golf ball or a golf ball that is struck into a strong wind. The idealizations made are useful ones. The utilization of a simple model that exactly describes the motion of an ideal golf ball enables an approximate description of the motion of actual golf balls in a useful range of cases. An explanation of the golf ball's trajectory that did not employ idealizations and that involved an attempt to include all causally relevant factors would be horrendously complex, if it was possible to calculate at all.

Galileo initiated the scientific revolution, in part, by legitimizing use of the abstract language of mathematics to enable the application of idealized explanatory laws and models in the natural sciences. Galileo's *Dialogue Concerning two chief world systems, Ptolemaic and Copernican* (Galilei, 1953) is a polemical work in which a proponent of the new approach to science, which employs idealization, argues against an advocate of the Aristotelianism of Galileo's day that was opposed to idealization in the sciences. In response to the major Aristotelian objection to idealization, that the physical world is not a world of perfect geometrical shapes and therefore cannot be accurately described in geometrical terms, Salviati, Galileo's proponent of idealization, draws an analogy between the 'geometrical philosopher' and a merchant who allows for the weight of packaging materials when calculating the weight of his wares:

> *… when he wants to recognize in the concrete the effects which he has proved in the abstract, [he] must deduct the material hindrances, and if he is able to do so, I assure you that things are in no less agreement than arithmetical computations. The errors, then, lie not in the abstractness or concreteness, not in geometry or physics, but in a calculator who does not know how to make a true accounting.* (Galilei, 1953, pp. 207–8)

The recognition that idealization is endemic to scientific explanation raises problems for the confirmation of theories. An empirical test is rarely, if ever, a decisive test of a theory. Instead it is a test of a conjunction of the theory plus a series of idealizing assumptions. A falsification of this conjunction implies that either the theory is false or that one or more of those idealizing assumptions are to be rejected. Unless the magnitude of the combined effect of all the idealizing assumptions that stand between a theory and empirical reality can be identified, or unless a theory that accurately describes reality without the aid of idealizing assumptions can be constructed, an exact experiment that decisively confirms or disconfirms a theory cannot be performed.

Idealization in Economics

The social science in which idealization is most obviously employed, and most explicitly defended, is neoclassical economics. This is because neoclassical economists make idealizing assumptions that are plainly false and in need of defense from attacks due to critics who object to economist's reliance on false idealizing assumptions. Most, if not all, of the generalizations that form the corpus of neoclassical economics are true only in idealized situations where fully informed, fully rational agents, who are concerned only with maximizing expected utility, trade in conditions of unfettered competition. Economic reality is very different from this idealized situation. The prices of actual goods usually do not vary in the ways in which the neoclassical laws of supply and demand suggest that they should, and real humans do not appear to act so as to always maximize expected utility. Many classes of ordinary human actions bear no apparent relation to the maximization of expected utility, and some classes of ordinary human actions appear to be negatively correlated with expected utility.

The most influential justifications of the use of idealization in economics have been conducted on Galilean lines and appear as part of a defense of economics as being methodologically similar to the natural sciences. A historically influential defense of idealization in economics is presented in John Stuart Mill's *On the Definition of Political Economy; and on the Method of Investigation Proper to It*. According to Mill,

> *That which is true in the abstract, is always true in the concrete with proper allowances. When a certain cause really exists, and if left to itself would infallibly produce a certain effect, that same effect, modified by all the other concurrent causes, will correctly correspond to the result really produced.* (Mill, 1967, pp. 326–7)

Mill notes the unreality of Euclidean geometry for "… lines, angles, and figures, as human hands can construct" (Mill, 1967, p. 327), and draws an analogy to the situation of the 'political economist':

> *No mathematician ever thought that his definition of a line corresponded to an actual line. As little did any political economist ever imagine that real men had no object of desire but wealth, or none which would not give way to the slightest motive of a pecuniary kind. But they were justified in assuming this, for the purposes of their argument; because they had to do only with those parts of human conduct which have pecuniary advantage for their direct and principal object; and because, as no two individual cases are exactly alike, no general maxims could ever be laid down unless some of the circumstances of the particular case were left out of consideration.* (Mill, 1967, p. 327)

Mill's defense of idealization ties its use to a metaphysical picture of the world as being composed of causal tendencies that continue to be efficacious when they are not being interfered with by the activity of other causal tendencies (Hausman, 1992, pp. 33–53). This is a metaphysical picture that has been argued for in contemporary times by Cartwright (1989), whose Millian heritage is quite explicit.

While Mill argued for the general legitimacy of idealization, Marx (1968) went further and attempted to demonstrate the ways in which idealizational explanations in the social sciences could be rigorously tested, or at least this is how he has been interpreted by Leszek Nowak. According to Nowak, Marx should be recognized as 'the Galileo of the social sciences' because his application of Galilean idealization to the social sciences is the first instance of the use of rigorous scientific

reasoning in the social sciences (Nowak, 1980, p. 38). Nowak's Marx relates idealizational generalizations to real situations in which these can be tested, by identifying each interfering cause that affects the expression of an underlying factor represented by an idealizational law, and attempting to calculate the magnitude of the effect of each such interfering cause.

Nowak interprets Marx's presentation of the law of value – a law relating the value of a commodity to the amount of labor devoted to its production – as an attempt to show how this idealized law could be used to explain the actual price of that commodity, in particular economic circumstances. According to Nowak, Marx's law of value is strictly true only when adjustments are made for eight factors that can affect actual economic situations. For example, the law of value applies when the supply and demand of a commodity are exactly balanced, but ordinarily this is not the case and an imbalance between supply and demand will tend to distort the value of commodities. If the magnitudes of all factors that can distort the value of a commodity are identified, then actual market prices can be explained and decisive tests of the idealized law of value produced, or so Nowak's Marx would argue. Marx and Mill are only some of the better known defenders of idealizations in economics. More recent defenses have been provided by Lionel Robbins and Milton Friedman, among others (Hamminga and De Marchi, 1994).

Opposition to the use of idealized explanatory models and laws, in economics and other social sciences, is often tied to broader concerns. In particular, some opponents of the use of Galilean idealization in the social sciences attempt to draw a sharp distinction between the methods appropriate to the social sciences and those appropriate to the natural sciences. One influential way of pursuing this line of reasoning is to hold that naturalistic explanations are inappropriate in the social sciences where interpretive understanding is the appropriate methodological framework. On some such views, explanatory laws and models are out of place in the social sciences, and the fact that these are idealized only serves to demonstrate how unrealistic and inappropriate they are in the social sciences. The possibility of a sharp methodological divide between the natural and the social sciences has been attacked by methodological pluralists who want to recognize the potential legitimacy of a range of methodologies in both the natural and the social sciences (Bohman, 1991). If methodological pluralists are right, then there is no reason to think that idealized nomic explanations are generally inappropriate in the social sciences, although they may be inappropriate in some social sciences, or in some aspects of social science. The legitimacy of idealized nomic explanations in the social sciences is also defended by philosophical naturists, some of whom have provided explicit defenses of the utility of idealized explanatory laws in the social sciences (e.g., Kincaid, 1996; McIntyre, 1996).

A focused attack on the use of idealized explanations in neoclassical economics has been put forward by Hollis and Nell (1975), (pp. 43–6). These authors draw a distinction between the practical application of idealizing explanatory assumptions, such as the idealizing assumption of frictionless motion in physics and the practical application of idealizing explanatory assumptions in neoclassical economics, such as the idealizing assumption that adequate information about the market is available to all participants. In the case of frictionless motion, a clearly defined variable, the coefficient of friction, which can be accurately adjusted for, is assumed away. Actual participants in actual market places often have inadequate information about the market and as – in contrast to the case of frictionless motion – the effects of inadequate information are not well understood, it is practically impossible to adjust real data to precisely test explanatory laws and models that make the idealizing assumption of adequate information.

Hollis and Nell are right that the effects of inadequate information cannot be easily measured and adjusted for, whereas the effect of friction on the motion of objects traveling along a plane can. However, the simplicity of the frictionless plane is atypical of idealizations in the natural sciences, where approximations and adjustments for factors that are not fully understood are frequently made (Cartwright, 1983, 1989; Laymon, 1995). If it is accepted that idealizations are being inappropriately used whenever the effect of interfering factors cannot be quantified – an assumption that Hollis and Nell appear to make – then considerations of consistency suggest that the results of a very large proportion of the natural sciences ought to be rejected on the very same methodological grounds.

Ideal Types

Although it did not originate with him, the notion of an ideal type has come to be associated closely with Max Weber, and it occupies a central place in his thinking about social scientific methodology (Weber, 1949, 1968). Weberian ideal types are a form of idealization that Weber thought to be important in, and distinctive to, the social sciences. Ideal types in the social sciences play many of the explanatory roles that idealizations in the natural sciences play. They are used to identify and separate underlying causal factors that are obscured by the interplay of causes that contribute to the makeup of complex social environments. When messy, complex data about social environments is appropriately simplified by abstraction, useful ideal types can be identified that enable powerful explanatory generalizations to be developed.

Weber is at pains to ensure that ideal types not be understood as averages, or as direct attempts to form empirical social generalizations:

> *It is thus the "idea" of the historically given modern society, based on an exchange economy, which is developed for us by quite the same logical principles as are used in constructing the idea of the medieval "city economy" as a "genetic" concept. When we do this, we construct the concept "city economy" not as an average of the economic structures actually existing in all the cities observed but as an ideal type. An ideal type is formed by the one-sided accentuation of one or more points of view and by the synthesis of a great many diffuse, discrete, more or less present and occasionally absent concrete individual phenomena, which are arranged according to those one-sidedly emphasized viewpoints into a unified analytical construct. In its conceptual purity, this mental construct cannot be found empirically anywhere in reality.* (Weber, 1949, p. 90)

Like idealizations in the natural sciences, ideal types can perform explanatory work at a number of different levels of generality, and can do so in a number of different ways. Weber employs the concept of the ideal type in several different ways

(Burger, 1987, pp. 130–5). First there are 'individual ideal types' which can play a role in clarifying conceptions of specific historical phenomena. Even if there is no actual instance of the pure individual ideal type 'feudalism,' it aids historians in understanding feudal societies, and the era in which feudalism was prevalent, if they can see how and where particular societies approximated to the ideal type feudalism. Second, there are 'generic ideal types' which describe the underlying causal factors that influence many or all societies. Here Weber would include the idealizations that constitute the 'fundamental concepts' of economics (Weber, 1949, p. 100). A third role for ideal types is to describe developmental sequences relating successive historical epochs. Marx's postulated historical sequence leading to the development of a pure socialist society is an example of ideal types playing this role. In all these roles ideal types are not obviously different from idealizations in the natural sciences, which can also be specific, generic, or developmental. However, there is a fourth way in which ideal types are used in an explanation that appears to distinguish them from idealizations in the natural sciences, and this is when they play the role of 'essential' ideal types.

Essential ideal types encapsulate the ideas that are characteristic of the thinking of a particular group of people and that imbue their thought with meaning. If the pre-Raphaelite art movement of the nineteenth century is to be properly understood, for example, it will not be enough only to examine actual instances of pre-Raphaelite art. The ideal type of art that the pre-Raphaelites were striving to perfect will have to be understood. It may well be that no single pre-Raphaelite artwork completely succeeded in capturing the artistic ideals that the pre-Raphaelites aimed to achieve. Nevertheless, there is no hope of understanding the pre-Raphaelite art movement, and its causal interactions with other art movements and with the wider world, unless the expressive aims of its participants are understood. The same is true of broader and more complicated intellectual movements such as Christianity and Communism.

The ideal type is a form of idealization that enables causal explanations to be employed in the social sciences, and it can also be employed as an explanatory form that gives a distinctive place to subjective human interpretation. Because it brings together causal explanation and meaningful human interpretation, the ideal type's use by Weber can be understood as a means to find middle ground – and here Weber anticipates Davidson's subsequent work on reasons and causal explanation (Ringer, 1997, p. 172) – between methodological dualist interpretivists, such as Dilthey, who draw a sharp divide between natural scientific explanation and social scientific understanding, and methodological monist positivists and naturalists, such as Hempel, who typically seek to subsume social scientific concepts under natural scientific categories. The actual role that Weber's discussion of ideal types played in the history of the intense and polemical methodological debates in Germany early in the twentieth century – the 'Methodenstreit' – is much more complex than this story allows, however.

Although ideal types continue to be a subject of considerable historical and sociological interest (e.g., Burger, 1987; Ringer, 1997; Runciman, 1972), they have rarely been discussed in recent philosophy of science and social science (exceptions include Papineau, 1976 and Weinert, 1996). In part this is because philosophical discussion of ideal types has mostly been subsumed into discussion of idealizations and in part it is because idealization has not been a focus of a great deal of discussion in twentieth-century and early twenty-first-century philosophy.

Ongoing Disputes

While it will be conceded by most that there are particular situations where idealizations can be useful in the provision of approximately accurate descriptions, there remains much dispute about the range of the utility of idealizational explanations. If idealized laws and models are to be reliably used in scientific explanation, the ways in which actual situations deviate from ideal ones need to be accounted for. A temptingly simple way of dealing with this problem, which is explicit in Nowak's treatment of idealization, is to understand each idealization as a limit of a series of real cases and make adjustments accordingly (Nowak, 1980). Sometimes this approach is appropriate. The frictionless plane is a limit case of a series of actual planes that are successively less affected by friction. So it is a simple matter to correct for the effect of friction to precisely explain actual cases. However, scientists often have little idea of how to go about correcting for idealizations in order to accurately describe real situations (Cartwright, 1983, 1989; Laymon, 1995).

In the experimental sciences, the gap between idealizations and the reality they are intended to help describe can be reduced by designing more complex experiments that involve fewer idealizations to relate to reality. In addition, experimental situations that eliminate or minimize the effect of interfering causes can be set up, thereby reducing the need to idealize (Laymon, 1995). While these approaches will typically reduce the magnitude of the deviation of idealized explanatory laws and models from reality, there remain a number of problems with their application. First, scientists do not appear to construct complete lists of the causal factors that might interfere in experiments. Indeed, it is not clear that they could do this. Second, causal factors do not always interact in an additive way, so their combined effect resists simple calculation. A third problem is that there is an explanatory cost involved in the use of highly specific experiments. The explanations arrived at are applicable to a narrower band of cases. The cost of accuracy is the loss of generality.

In the social sciences there are moral and practical barriers to experimentation. However, idealizations and explanatory appeals to ideal types remain omnipresent in social science explanations. While the gap between idealized explanations and the real situations that they can be applied to can be reduced in the experimental sciences, there is often little hope of bridging the equivalent gap in the social sciences. Social scientists appear to be stuck with the choice of either admitting that their preferred idealizations may be wrong-headed or insisting, without apparent justification, that these must be accepted a priori. However, idealizations can go wrong (Cartwright, 1995), and it seems a mistake to try to disallow this possibility by appealing to a priori justification. Nowak's Marx attempted to abstract from the actual circumstances of nineteenth century capitalist economies to the law of value.

Neoclassical economists, who deny that economics should concern itself with the concept of value at all, would say that this is a paradigmatic example of idealization gone wrong. What guarantee do neoclassical economists have, or could have, to hold that their preferred idealizations stand on a surer footing?

A further subject of dispute centers on a metaphysical consequence of the prevalence of idealization in science, which has been raised against scientific realists by Nancy Cartwright (1983, 1989), reviving and developing the antirealist thinking of Pierre Duhem, the French physicist and philosopher who wrote at the end of the nineteenth century. Cartwright (1983) agrees with scientific realists that the fundamental laws of science provide the basis for explanatorily powerful generalizations but denies that this in itself is a good argument for their truth-aptness. The fact that fundamental laws are idealized means that they are protected from direct empirical testing by loose approximations, the use of open-ended *ceteris paribus* clauses, and the unrealistic assumption that causal factors are straightforwardly additive. Scientific realists such as Liu (2004) and Weisberg (2007) generally concede that these problems exist, but argue that nonfundamental laws in science, which are special instances of more fundamental laws, are more amenable to testing and can be better confirmed. However, Cartwright denies that actual nonfundamental laws in the natural sciences are literally to be understood as logical derivations of fundamental laws. In a careful study of the construction of amplifiers, Cartwright (1983, pp. 107–12) demonstrates how engineers approximate away from general theory in ad hoc ways so as to find descriptively accurate laws that have only the appearance of being logically derived from general laws.

Scientific realists can accede to all of Cartwright's points and hold out the hope of improving experimental techniques, thereby improving scientific explanations to the point where there is less room for doubt as to the veracity of fundamental laws. However, because of a lack of controlled experimentation in the social sciences, the social scientist who is a realist about particular grand theories in the social sciences is faced with the same problem without apparent hope of a solution. No progress is made toward demonstrating that a grand sociological or economic theory is true by showing how it is applied in a particular situation to provide a more specific theory, which is empirically well established, if the application of the grand theory to the particular situation turns out to depend on ad hoc modifications and is not an instance of logical derivation. However, few, if any, specific social scientific theories appear to be logically derived from grand theories.

Identity and Identification

Akeel Bilgrami, Columbia University, New York, NY, USA

Published by Elsevier Ltd.

Abstract

A distinction is made between subjective and objective identities and each is explored in the rest of the article, with a view to elaborating its philosophical significance and its relevance to politics, culture, and psychology.

One initial step toward imposing some theoretical order on the notoriously haphazard concept of 'identity' in politics and culture is to distinguish at the outset between its 'subjective' and 'objective' aspects. When a person is said to have a certain identity owing to some characteristics he or she has, and with which he or she identifies, then identity is being thought of in its subjective aspects. If a person is said to have a certain identity owing to some characteristics he or she has, but with which he or she does not necessarily identify, then we are speaking of his or her objective identity.

Subjective Identity, First

Subjective identity is the notion of identity that is most immediately relevant to politics because people sometimes tend to allow themselves to be mobilized in the public arena on its basis. It is not – not by any means – that subjective identity is always mobilized in politics. It is more that, where it exists, it is poised so as to be mobilized if other conditions are present.

What is it to identify with some characteristic one possesses, thereby making it an identity-imparting characteristic in the subjective sense? This is a more complicated question than it might seem.

A first stab at answering it might be to say that someone identifies with a certain characteristic, if she values it. Thus one must value the fact that one belongs to a certain nationality or ethnic community or even a certain profession, if one can be said to have the identity (in the subjective sense) of an Indian or Korean-American, say, or a teacher and writer. That seems to be a minimal initial condition for identifying with it. But it is clearly not sufficient, because one may have values from which one is oneself alienated. This can be a fairly common phenomenon. To be alienated from one's values is structurally akin to being alienated from one's desires. Just as an alcoholic may be disgusted with his addictive desire for alcohol, so also someone may disapprove of his own patriotism or find his pride in his profession intolerably smug.

So a further condition has to be added to our minimal condition before a characteristic imparts subjective identity. One has to endorse one's valuing of that characteristic. That would presumably ensure that one is not alienated from its valuing. There is another reason why endorsement of this kind is necessary apart from the attempt to solve the problem of values one is alienated from. The topic of *subjective* identity is not merely about what one is but also about what one conceives of oneself to be. This idea, therefore, brings with it, in any case, the reflective endorsement of the relevant valued characteristics.

To endorse a value, it is often said, is to have a second-order value. Someone must value the fact that he or she values the characteristic of belonging to a certain nationality or profession, before he or she can be said to have the identity of an Indian or a teacher, in this subjective sense. (We should add that something like a second-order valuing may not be necessary in order to ensure that there is no alienation from one's own first-order values; all that may be needed is something negative: that there is no second-order disapproval of one's first-order value. However, as just said, the second-order level comes in a more positive form, in any case, because subjective identity is unavoidably about reflective matters such as what one takes oneself to be.)

With this second-order valuing in place, have we said something sufficient about subjective identity? Not yet, because one's second-order values can be highly neurotic, and when they are, they can be values that one is also alienated from. For example, someone may feel his second-order value, which disapproves of his first-order valuing of his role in his profession as being too smug, as itself being too prim, too censorious, and too much of a super-ego phenomenon.

What still further condition must now be added to give a sufficient account of subjective identity? One possibility is to conceive of it as requiring a receding hierarchy of orders of value. At each order, one is not alienated from a value if one endorses it at a higher order. So in our example, any neurosis regarding a person's second-order disapproval of his pride in his profession is ruled out, if he has a third-order approval of his second-order disapproval. This solution raises worries about an infinite regress.

In order to avoid such a regress, a second possibility is to conceive subjective identity not as emerging in a receding hierarchy but as requiring a coherence among one's values, no matter what order of value is being considered. So in our example, the second-order disapproval is neurotic, not because there is a lack of third-order approval of the second-order disapproval, but rather because the latter does not cohere with one's other values at all levels, including the first-order values. The second-order disapproval is something that one is not alienated from, something that one identifies with, only if it coheres well with the first-order values and other second-order values one has. Here no infinite regress threatens, but some philosophical account of coherence among values must be worked out to match the coherentist accounts of belief and

knowledge that we already have available with some degree of sophistication. It is worth noting that if this coherentist way of thinking of subjective identity is right, it is very closely tied to rationality in values, since the point of a coherentist account of value is presumably that it is an account of when one's values are rational. In a word, one identifies with one's values to the extent that the value is rational, in the sense of being fortified by coherence with our other values. The conclusion is attractive like any conclusion that allows two seemingly separate themes (rationality and subjective identity) to be united.

The trouble, however, is that if subjective identity is given by a rationality-imparting coherence among our values, then we will be identified with all the values we have that are rational in this sense. But that is of not much help with the idea of identity, because it follows from this that our identity (in the subjective sense) is never going to be anything very distinctive. It will pick out nothing very special or identity-imparting among all our coherent values, such as the ones we have been discussing: one's valuing the fact that one is an Indian, a teacher, a writer, a Muslim; no one of these will be more importantly relevant to one's identity than other characteristics of ours that we value coherently, such as one's weight, one's love of cricket or of dessert. Precisely what seemed attractive about this view is what makes it of no particular help on the subject of identity, with which we are concerned.

Perhaps this difficulty teaches a deflationary lesson. Perhaps it is a sign that there is something inflated about the very idea of identity, that our thinking there is something specially distinctive about some characteristics is misguided, that it is not something we should expect, and that we have come to expect it only because of the recent rise of 'identity' politics that has elevated some characteristics – nationality, ethnicity, linguistic and religious allegiances – beyond anything warranted by or echoed in the actual moral-psychological economies of ordinary citizens. There is some point to this qualm, a point in fact that needs much nuanced development in longer discussions of the subject. But it can also be a point that is too glibly made. For it does seem, at first sight anyway, to be quite accurately descriptive of at least a small, vocal, and influential body of citizens in many polities that they display a strong identification with these very characteristics and allow themselves to be mobilized on its basis. And of them, at least, some notion of identification must be given, which shows why these characteristics are valued more distinctively than the many others that are also coherently and rationally valued by them.

We are, therefore, still lacking a sufficient account of subjective identity. To repeat: what we need is not merely endorsement (of one's own valuing of some characteristic of ours) by some higher order values or by coherence with other values, but some further element that makes the value endorsed more central and distinctive in our psychological economies.

An obvious thought here might be to say that the values that are more central are those that are more *intense* than other values, especially since it does seem as if Muslims, Quebecois, Serbians, and so forth who seem most visible in identity politics value their Muslimness, and so forth, very intensely, more intensely than other things they value. It is a question, however, how theoretically useful it is to plonk down 'intensity' as a primitive and unanalyzable property that values have; but even apart from this problem, the thought is wrong, for in some cases of weakness of will, we act on values that are very intense but that we do not endorse.

A better thought at getting at the required further element is to say that the endorsement of the value must be such that it makes the value concerned, in some sense, more *unrevisable* (rather than more intense) relative to the other values one holds. For it is surely intuitive that a Muslim or Quebecois, whose identity is caught up with his valuing these characteristics of his, is less likely to give up valuing them than the other values he holds, or perhaps – a more subtle variation of the intuition, one that will be developed briefly below – is less likely to *conceive of himself* as giving up the value.

For this thought to be genuinely promising, we need (1) to show what sort of endorsement of a value makes the value relatively unrevisable and (2) to ground the idea of unrevisability in something that would not show the reluctance to revise to be irrational by the lights of the agent herself (in the way cases of weakness of will show that acting on or even holding some of our most intense values is irrational by the agent's own lights).

The task identified as (1) in the preceding paragraph is the most significant: which among all the values that equally cohere with one another are the more unrevisable? As we said, it is only if we answer this question that we would have captured what is distinctively identity-imparting about valuing being a Muslim or Quebecois, for the sort of agent we are concerned with. Here is a way of bringing out why that should be so. Any answer to the question would have an analogous effect to what Quine intended when he argued that some beliefs or propositions are in the very center rather than further out toward the periphery in our physical theory. The idea behind this metaphor was intended to replace misguided traditional ideas of 'analytic' propositions. His point was that for the theory to be the theory it is, is given by the beliefs or propositions that are at the center of our physical theory (e.g., our belief in the transitivity of length), since they are more immune to revision than the ones further out on the periphery, which are more exposed to what Quine called the 'tribunal of experience.' If those central beliefs do get revised, then it is not clear whether the theory has been changed or whether we have changed the subject because the meanings have changed. So also, analogously, we might say that a person's identity is given by his or her relatively unrevisable values – however we characterize them – and if those are given up, then it is not clear whether it is a change in the ordinary sense where the overall identity remains constant, but a change in value takes place, or whether the overall identity itself is changed. This analogy, though inexact, is all the same roughly intuitive and reflects our ordinary talk, when in a fit of nationalist sentiment, we say things such as 'I will lose my sense of self, of who I am, if I betray my country' (or, as in Forster's British schoolboy morality, 'I will lose my sense of self, I will not recognize who I am, if I betray my friend'), the sorts of things we are not likely to say of other things we value. Compare these to, 'I will lose my sense of self, if I give up my love of desserts,' which because of its implausibility shows such first-order values to be more analogous to beliefs or propositions at the periphery for Quine. (These are mere examples intended to convey the structural point of the analogy intuitively. Of course, it is possible,

though perhaps not routine, that someone may value his sweet tooth in the way a stereotypical nationalist or British public schoolboy values country or friendship, that is, analogously to Quine's center of the web rather than the periphery. The possibility in no way spoils the analogy; it merely shows that identities might be eccentric or bizarre on occasion.)

So much for the significance of unrevisability. But task (1) above was the task of defining it. We are seeking to define a way of endorsing one's valuing of some characteristic one possesses, which shows that value to be relatively unrevisable compared to other values one holds. Because we have already seen that coherence cannot provide such a special way of endorsement, let us return to the idea of second-order valuing of a first-order value to explore the sort of endorsement needed. What do we need to add to a second-order value to make the first-order value endorsed (relatively) unrevisable in one's psychological economy? An example may help to make the question and an answer to it less abstract.

Let us take some of the more absolutist Muslims in Iran over the last two decades. They have often urged something that approximates unrevisability of their Islamic values. One way they have done so is to argue that Iran needs to protect itself – in fact not just others in Iran, but even they the absolutists themselves – should protect themselves against their own 'moral' weakening and corruption in the face of the inevitable spread of the pernicious values of modernity in general and the West in particular. And they have argued (like Ulysses did, anticipating the sirens) that this protection should be ensured by entrenching Islamic values so deeply now that were Muslims even to be so weakened, the social, political, and legal institutions would not make it easy for them to shed their Islamic ways of life. Such a form of endorsement of one's Islamic values vividly shows it to be more unrevisable (in a very special sense) than other values one has and endorses having. Consider that the endorsement takes a counterfactual form: we value something in a way that we want ourselves to be living by the value, even if we (counter to present fact) do not value it anymore. At the time of valuing it, then, such a value stands out as very distinctive. The sort of unrevisability here is quite special because it is not so much that the value (at the first-order level) itself is permanent or immutable, but even though we may revise things later and cease to value it, the fact is that at the time of valuing it in this way, one (at the second-order level) yearns for the value to be unrevisable and relatively permanent, unlike all the other values that we endorse in the more ordinary way. That surely makes it part of one's deepest self-conception, because one would so utterly disapprove of oneself if we did not have the value at some future point, that we now try and make sure that one's self, at that future point, will live according to the value. 'Identity-imparting,' 'self-constituting,' and so forth, seem apt descriptions for values held and endorsed with such deep commitment.

Task (2) remains. Not all values that are unrevisable in this way are rational. What needs to be added is that these unrevisable values must also cohere with our other values. Coherence of a value, conceived as unrevisable in this special sense, with one's other values, allows for the rationality of this form of unrevisability, because reluctance to revise could only be irrational if the value one does not revise is one that does not have rational support from one's other values.

Before closing the discussion of subjective identity, one important cautionary remark should be made to protect against a misunderstanding of the notion as just defined. One should not be put off by the specific example given above, to think that the sort of endorsement that generates identity in this way, is a sign of fanaticism or illiberalism, just because we have become used to thinking of Islamic absolutism to be fanatical and illiberal. That would be to allow substantive opinions to blind us to the merits of the theoretical analysis we have come to, that is to say, blind us to the structural feature of the endorsement of a value that generates subjective identity. After all, the special way we value our own basic constitutional rights reflects just such an endorsement of our own identity-generating values *as liberals*, since all it does is reflect the same structure as the Iranian absolutists in the earlier example. We elevate a very few of the many values we more or less coherently hold to fundamental constitutional 'rights' – for example, free speech – precisely because we want to protect our future selves from giving in to any weakening of those values, as when in the face of strong dislike of another's substantive views, we might in the future find ourselves wanting to censor him. What our elevating these values into fundamental rights does is express the fact that we now want that we cannot later censor someone we strongly disagree with if we later have indeed weakened enough to wish to censor him. A liberal's deepest self-conception, that is, a liberal's identity, and a Muslim's identity, therefore – whatever the differences between them on other matters may be – is given by the same counterfactual structures of endorsing and identifying with their cherished values that our theoretical analysis has proposed. Neither is any more fanatical than the other, at least in matters of subjective identity.

Objective Identity, Next

When we turn to the objective aspects of identity, identification on the part of the subject in question with the identity-imparting characteristic(s) is not a necessary condition. Thus, for instance, racial identities when they are thought to be given by characteristics of descent, can be thought of as objective in this sense. Chromosomal criteria for defining gender identity are similarly objective. But biological criteria are not the only criteria that are routinely invoked. Inter-subjective and social criteria are also much favored. Thus, for instance, Marxists often claim that one's identity is given by one's role in a particular economic formation in a given period of history, that is to say, one's class identity, as 'class' is defined by Marx.

Many oppose the purely biological ways of thinking of various kinds of identity, such as racial and gender identity, claiming that these identities are 'socially constructed' by the perceptions and attitudes of one's fellows, by the zeitgeist of a particular period, by the conceptual categories and social institutions at a given time. Foucault and those influenced by him have made much of this and Foucault himself gave detailed historical and social accounts of particular concepts and institutions in Europe as determining identities. In fact, it is interesting that Foucault and his followers claim that it is not only the biological and other scientific criteria that are caught up in social factors of this kind, but the subjective ones we

discussed in the last section as well. These too are shaped by conceptual and institutional formations far removed and hidden from the exercise of our reflective self-understanding, thereby showing the ideals of individual autonomy that we assume to reside in the idea of identification, to be illusory. This article will not take up these issues raised by Foucault's influence.

It will look briefly instead at the motivations for looking at objective factors of identity at all, over and above the subjective ones.

Many subjects may identify with some characteristic that is not what is most salient about them to others, and it is thought important by many political philosophers that it is these latter that may often define their identity, no matter what subjects may conceive themselves to be. A good example of this can be seen in Stalin's well-known definition of a nation, which stresses the importance of historical and economic criteria for national identity, with a view to providing a corrective to what were seen as somewhat premature and ungrounded subjective identifications of nationality found in many secessionist demands in different parts of the world. Here the motivation for objectivist criteria of identity is (at least implicitly) political.

But underlying these is a more interesting theoretical rationale that points to important issues of a more philosophical nature. The claim that agents may have a certain identity even if they do not take themselves to do so, implies that what one takes oneself to be can be mistaken, a kind of self-deception, or at least a self-myopia (which may not always involve the motivated element often associated with self-deception, but involves at least the idea that one may sometimes simply be too deep for oneself – where 'deep' is not intended as a bit of eulogy.)

It would be philosophically clarifying to make a distinction between two different sorts of appeal to objectivist identities that are said to be (possibly) hidden from a subject's own self-conception. (1) One claim, the weaker one, is that subjects often betray signs of a certain identity in much of their behavior, even if they do not endorse and identify with what is reflected in their behavior. (2) The other, stronger claim does not even require that something in the subjects' behavior reflects the identity given by the unendorsed characteristic; rather the characteristic and the identity is given by the deliverances of some (social, political, economic, or biological) theory regarding these subjects.

1. The weaker claim, not surprisingly, is less controversial, because it requires that the characteristics of a subject that are going to define his identity are something that he at least reveals in his behavior. The subject may not endorse them, he may not even acknowledge them, but if the only good explanation of his behavior is that he has those characteristics, and if those characteristics are salient compared to others, then some claim can be made regarding how they impart his identity. Within this view, the more extreme cases will be where the subject does not even acknowledge the characteristics as being revealed in the behavior. Many of the identities that surface in Freudian and psychoanalytic theories make much of this sort of case (Oedipal, narcissistic identities). The less extreme cases will be those where there *is* acknowledgment of the characteristics, but no endorsement of them on the part of the subject. These are likely to be more common. What may be called 'silent' identities, as in 'silent majorities,' often consist of subjects who are not self-identified with a certain pattern of behavior, but will not be in any particular state of denial (as they are in the more extreme cases) about whether their behavior reveals the characteristics they are seen to have. It is very likely, for example, that many ordinary Muslims in Iran and other Islamic countries, who do not identify with absolutist or fundamentalist Islam, may all the same admit that much in their behavior mutedly plays along with the Islamist elements in their societies.
2. The stronger claim very often appeals to biological criteria, but is most interesting when it does not. Because the biological criteria are in any case usually caught up with social factors (see the point made about them above during the brief discussion of 'social construction' of identity), they will be ignored here. Perhaps the most well known, well worked out, and widely discussed of the stronger objectivist version of identity, which is not biologically based, is due to Marx and those influenced by him. What makes for having a class identity, say, a proletarian identity, is not any kind of self-identification with the working class, not even any behavior that suggests certain unacknowledged or unendorsed allegiances to that class, but simply the objective fact of having a certain place and function in the relations of production during the modern capitalist period of economic history. What is remarkable and controversial about this view, more so than anything found in claim above, is that something regarding the self and its identity is being attributed, without any basis or manifestation required in the conscious or unconscious behavior of the selves or agents concerned. A working-class person who exhibits no proletarian consciousness nor any of the solidarity and forms of behavior appropriate to the class, and none of whose behavior reflects an unconscious manifestation of such solidarity or consciousness, is nevertheless said to have proletarian class identity, albeit with a 'false consciousness.' It is only because he has this identity that there can be cause to call such a subject's consciousness 'false.' It is false precisely because he fails to conceive himself aright, fails to see his deepest self, which is determined by objective historical and material relations.

It is such a view of self and identity (where self and self-conception can come so radically apart) that filled Isaiah Berlin with anxiety in his discussion of 'positive liberty,' because what it encourages is the idea that the achievement of *self-realization* of individual citizens – that is, the achievement of their own autonomy and liberty (in the positive sense) – is now left to states or to the 'vanguards' of political parties, which lay claim to greater understanding of what some subject's self really and objectively is. From such a viewpoint, according to those alarmed by it, there is no paradox in the expression 'forcing someone to be free.' (Lenin's 'vanguardism' was frank about denying any such paradox.)

Underlying political anxieties of this kind is a more philosophical issue, which is much discussed in contemporary moral psychology, the issue of external as opposed to internal

reasons. An internal reason is a reason for one to do, believe, or value something, which appeals to some other evaluative element in one's moral-psychological economy. An external reason makes no such appeal to an internal element, it requires only some objective fact that need not even be recognized by the subject for whom it provides a reason. Thus in the orthodox Marxist tradition, a proletarian, given his historically determined identity, has (an external) reason to be a revolutionary even if there is no element in his moral-psychological economy that values it. Berlin's (1969) anxieties about statist tyranny carried out in the name of self-realization and positive liberty, were thus implicitly and more deeply about the very idea of external reasons, even though he never quite articulated them as having that underlying target; however, it becomes very explicit in a denial of the cogency of the very idea of external reasons in a brilliant essay by Bernard Williams (a philosopher much influenced by Berlin), though the point is marred in that essay by a somewhat confused equation of internal reasons with a Humean notion of value and motivation.

This last set of points provides a good resting point for this article on identity, which has distinguished fundamentally between the subjective and objective aspects of the concept. To a considerable extent, which of these two aspects we emphasize in our study of the concept will be a matter of theoretical decision, a decision which, in turn, depends on non-arbitrary philosophical considerations having to do, as we have just seen, with themes at some distance from identity, such as autonomy and moral reasoning. In itself, this is to be expected, because self, freedom, and reason have been closely connected themes in philosophy ever since Kant, both in the analytical and the European traditions of the discipline. Although much more needs to be said in detail to make the links between these themes perspicuous and explicit, it is safe to say that the more inclined we are to be uneasy about the idea of 'external reasons,' the more likely we are to stress the subjective rather than the objective aspects of identity.

Abstract

Identities can be based on our social group memberships. This requires investigation of how people self-define in social categorical terms, how these self-categorizations are produced and reproduced in everyday social practice, and how such social identifications are psychologically and behaviorally consequential. Work addressing these issues is discussed. So too is work concerning the importance of having one's identifications recognized by others, the role of social identities in social and political change, and the ways in which identities may be constructed so as to organize collective action.

The term 'identity' features prominently in everyday and in academic use. It can refer to an individual's personal and idiosyncratic self-conceptualization, but also to a sense of self based on group memberships (e.g., one's national identity). Such group identities can give rise to feelings of pride and joy, and motivate solidarity. However, it is also easy to find evidence of the degree to which people will, in the name of their group, harm others: as Sen (2006) puts it, "identity can also kill – and kill with abandon" (p. 1). People's behavior in terms of their group identities has long fascinated researchers and social psychologists have sought to explain what makes such behavior (whether positive or negative) possible.

Identity and Identification

In some respects, the power of group identities to motivate behavior (sometimes at considerable personal cost) is puzzling: often the bases for membership are not at all apparent. Take national identity. Although a series of necessary and sufficient criteria for national belonging is easily proposed (e.g., a common ancestry, language, culture, etc.), comparative analysis reveals no tangible characteristics essential to the maintenance of national consciousness. Accordingly, many return to Emerson's observation that "the simplest statement that can be made about a nation is that it is a body of people who feel that they are a nation; and it may be that when all the fine-spun analysis is concluded this will be the ultimate statement as well" (1960: p. 102).

Such observations underline the relevance of social psychological theories of group behavior that emphasize the importance of considering how individuals conceptualize themselves in terms of social categories. Indeed, contemporary social psychological theory implies that rather than taking the existence of groups for granted, we need to explore how people self-define in social categorical terms, how these self-categorizations are produced and reproduced in everyday social practice, and how such social identifications are psychologically and behaviorally consequential.

The Social Psychology of Identification

The social psychological concept of social identity developed out of a sense of dissatisfaction with attempts to explain intergroup phenomena in terms of personal and interpersonal processes. Tajfel (1978) drew a distinction between individual-level and group-level processes, which was developed by Turner and elaborated in what became known as self-categorization theory (Turner et al., 1987). This tradition emphasizes the role of social categories in self and other construal. It argues that the self and others may be defined at different levels of abstraction. Sometimes this may be in terms of individual uniqueness. At other times it may be in social categorical terms (e.g., 'us' as Europeans, as Hindus, as supporters of Barcelona football club). This shift in the salience of individual-level and group-level self-definitions is psychologically important: defining oneself in terms of a social category makes group behavior possible and underlies the behavioral shift from individual to group behavior.

Central to Tajfel and Turner's approach is the idea the group behavior arises from our knowledge of our membership of social groups and the meaning that such memberships have for us, and they repeatedly emphasized that this involves processes that cannot be reduced to those involving individuals' personality characteristics. Specifically, group members' behavior is shaped by their social categorical representation of who they are in relation to others such that when one adopts a particular social categorical self-definition, one no longer thinks of oneself in terms of one's unique individuality, but thinks of oneself as a category exemplar. This entails conformity to one's cognitive representation of the beliefs, values, and norms stereotypically associated with that identity.

This logic applies to both the small face-to-face groups that have predominated within social psychological research and also to the mass social phenomena associated with large-scale social categorizations. With regards to the former, whereas previous social psychological theories of group behavior tended to see groups as aggregates of individuals (and accounted for group behavior in terms of the relations between such individuals), contemporary theory conceptualizes group membership in cognitive terms. With regards to the latter, once group behavior is seen to depend upon an act of identification with a social category rather than the prior existence of bonds between individuals, we can understand how what Anderson (1983) calls 'imagined communities' can exist and structure our sense of who we are and how we relate to others. Such identifications are not dependent upon interindividual relationships, nor are they in any sense primordial 'givens': they

too are socially produced self-categorizations. It is important to emphasize that there is no sense in which social identities are to be regarded as superficial. They are simultaneously social yet deeply felt.

Identity-Related Processes

The behavioral outcomes associated with identifying in terms of a social category are diverse. If there may be pride and joy, so there may be hate and derogation of the other, and many have assumed these to be inextricably linked such that the price to be paid for pride in the group is a degree of hostility toward those outside it. However, the diversity in the identity–behavior relationship shows this is simplistic: if some acts of social identification can result in hostility to an out-group, others do not. For example, in the UK there is no simple relationship between participants' level of social identification with the nation and prejudice toward immigrants and asylum seekers: rather, this relationship depends on how the contents of this national identity are defined (Pehrson et al., 2009). This implies that rather than seeking to uncover simple relationships between identifying in terms of a social group membership and particular behavioral outcomes (e.g., ethnocentricism), it is more appropriate to theorize the social psychological processes involved in adopting a social identification and then to explore how, in different contexts, these same processes may support and sustain quite different behaviors. Or to put it another way, rather than seeking generality in terms of the actions that flow from collective identities, generality may better be conceptualized in terms of the generic processes that allow group behavior of any sort (Reicher and Hopkins, 2001).

With regards to these generic processes the most basic is the concept of "depersonalisation" (Turner et al., 1987). This conveys the idea that when acting in terms of a social identification we no longer view ourselves and others in terms of our individual characteristics but see ourselves in terms of our shared social identification. Indeed, people's behavior is no longer guided by their idiosyncratic beliefs and dispositions but conforms to their cognitive representation of the values and norms associated with that collectivity. Moreover, to the degree that a common categorization becomes psychologically salient, others judged as sharing that social self-definition are regarded as one's fellows (even to the extent that we will regard ourselves and our fellows as interchangeable exemplars of that social category).

This has several consequences. To the degree one shares a social identification with others one expects to agree with them and is more likely to be influenced by them than those categorized as out-group (Turner, 1991). Moreover, to the degree that individuals share a common social identification they are more likely to respect each other, cooperate with each other, and help each other. Research also shows that the cognitive and relational changes associated with adopting a shared social identification with others allows those involved to align their goals and interests, and to coordinate their actions so as to enact their social identity. In addition to being psychologically rewarding and empowering, this can feed back into participants' identity commitments (Drury and Reicher, 2005).

The benefits of a shared social identification should not be underestimated. Much research shows the importance of social relationship for well-being, and social identity researchers have shown that one's social identifications contribute to well-being because they lead people to expect support from their fellow group members (Jetten et al., 2012). It has even been found that participating in mass collective events characterized by a shared social identification (such as a pilgrimage event) can bring benefits to well-being (Tewari et al., 2012) and that the emergence of a social identity in an emergency can improve resilience (Drury et al., 2009).

What then about how such processes shape intergroup relations? Tajfel argued group members make intergroup comparisons and seek to establish their group's positive distinctiveness in relation to other group identities. Some researchers have interpreted this implying the derogation of an out-group. However, this is misleading: intergroup differentiation is a process and not a specific behavior, and the behavioral outcomes observed depend upon the norms and values of the relevant identity (Reicher and Hopkins, 2001). Again, we are drawn to social, cultural, and political factors, and to how these shape people's understandings of themselves and others.

Social Identification in Context

As should be apparent by now, an account of identity that emphasizes the importance of addressing an individual's cognitive representation of themselves does not constitute a retreat to a psychologism in which what goes on in people's heads is privileged over what goes on in the social context or in public (Brubaker et al., 2004). Indeed, Brubaker, et al. argue that the promise of a cognitive approach to identity is that it "may help connect our analyses of what goes on in people's heads with our analysis of what goes on in public" (p. 46). For example, it draws our attention to the social practices that support and sustain particular self-definitions. It is through such group-making activities (e.g., the practices of "banal nationalism," Billig, 1995) that self-categories are produced and reproduced, and made psychologically relevant. It also draws attention to how participation in collective events may revivify social bonds and social identities.

Sensitivity to the contingency of social categorization on the social practices associated with any context also helps explain the variability in any individual's self-categorization. In different contexts, different self-categories and group memberships can be psychologically salient (for we can conceptualize ourselves in multiple ways). Doubtless individuals vary in the degree to which they invest in different categories. Yet, situational factors are important in determining the salience of any potential self-categorization (Turner et al., 1987). Indeed, unless there is some match between one's social identification and the context in which one must operate, that identification will have little value or utility in navigating that environment and guiding one's behavior. Moreover, as other people are elements of the social context, it follows that their behaviors are relevant to how one conceptualizes oneself. Take, for example, the degree to which others' behavior

validates one's self-conception. Identity certainly involves an individual's subjective identification with a group. However, if such an identification is to be meaningful and sustainable, it must be validated by others. This insight has a long history in sociological thinking, which routinely emphasizes the importance of the social performance of identity and the recognition of that performance by others. Indeed Jenkins (1996) explains "*social identity is never unilateral*" (p. 21, original emphasis) with the corollary being that to speak of someone as 'having an identity' it is important that others treat that person as having that identity. Being treated by others in terms of a category that is discrepant with one's own self-conception is aversive and people use social interactions to elicit feedback that sustains their self-conceptions (Swann, 1987). For example, people may signal their social identifications (e.g., through their clothing) so as to elicit others' recognition that they are to be taken as members of a particular group (rather than another) and such research shows that this recognition is important for the individuals' subjective experience of that social identification (Hopkins and Greenwood, 2013).
